Emission Cross-Sections of N_2 in the Vacuum

Ultraviolet by Electron Impact

Thesis directed by Professor Charles A. Barth

An electron beam excitation chamber was designed and constructed for the measurement of emission cross-sections by electron impact excitation of gases. The electron beam excitation spectrum of N at low pressure (0.12 microns to 0.18 microns) in the wavelength range 1200 Å to 2000 Å was recorded for monoenergetic electron impact energies from 10 eV to 208 eV. The spectral features observed were the Lyman-Birge-Hopfield vibrational transitions (a $^1\Pi_g \rightarrow X^1\Sigma_g^+$) and several atomic nitrogen lines produced by dissociative excitation of N2. The radiation detection system consisted of a McPherson 218 monochromator and a 541 G-08-18 EMR photomultiplier.

The emission cross-sections of the vibrational transitions of the $a^1\Pi_g$ state of molecular nitrogen were measured. The transition is predominantly magnetic dipole. The emission cross-sections of the vibrational transitions were summed to give total emission cross-sections for each of the first seven vibrational levels and for the total electronic transition. The measured cross-sections were

apparent cross-sections, uncorrected for cascading. The peak cross-section was at 15.5 $_{\pm}$ 1.5 eV and had a value of 3.85 x $10^{-17}~\rm cm^2$ for the total electronic transition. The maximum cascade contribution was estimated to be 29%. The actual cascade contribution was probably much less.

The geometrical problem of determining the fraction of the Lyman-Birge-Hopfield (LBH) spontaneous radiation detected was solved. An N $_2$ molecule excited to a vibrational level of the a $^1\Pi_g$ state can travel several centimeters before radiating, because of the long lifetime of the state (80 microseconds).

The atomic nitrogen transitions studied were the multiplets at 1200 Å ($^4\text{P} \rightarrow ^4\text{S}^{\text{O}}$), 1493 Å ($^2\text{P} \rightarrow ^2\text{D}^{\text{O}}$) and 1743 Å ($^2\text{P} \rightarrow ^2\text{P}^{\text{O}}$). These transitions in atomic nitrogen were caused by dissociative excitation of molecular nitrogen, one of the products being an excited nitrogen atom in a ^4P or ^2P state. The transitions were permitted electric dipole transitions. The emission cross-sections of these multiplets of atomic nitrogen were measured. The cross-sections typically had two thresholds, one at about 20 eV due to dissociative excitation of N₂ into two nitrogen atoms, and the other at about 35 eV because of dissociative ionization excitation of N₂ into a nitrogen atom and a once ionized nitrogen atom. The sum of the two types of dissociative excitation cross-sections was the measured quantity. The peak cross-section for these dissociatively excited transitions was at about 110 eV.

The results of the experiment were applied to the photoelectron excited dayglow and to the aurora to determine emission rate factors.

This abstract is approved as to form and content.

I recommend its publication.

Faculty member in charge of thesis

ACKNOWLEDGEMENT

The author expresses his appreciation to many people whose combined efforts made this thesis possible. Special thanks go to Dr. Charles A. Barth, Mr. David Rusch, Mrs. Maureen Anderson, Mr. Wallace Crandall and Miss Jacqueline Myers. I thank Dr. Barth for suggesting the project, and his support throughout the project. I thank Dave Rusch for his help in writing the computer programs, especially the plotting routines. I thank Maureen Anderson for reducing most of the experimental data. I thank Wally Crandall for his help in setting up the vacuum systems. I thank Jacqueline Myers for typing the final draft of the thesis.

I thank Drs. Ian Stewart, Gordon Dunn, Gary Thomas, Ted Speiser and Manfred Rees for serving on my thesis committee.

I thank Mrs. Meredith Murbach for her help in programming the geometrical calculations.

I thank Mr. Ray Ruehle for his assistance in the absolute calibration of the photomultiplier tube.

CHAPTER I

INTRODUCTION

1.1 Historical Review

The Lyman-Birge-Hopfield ($a^1\Pi_g \longleftrightarrow X^1\Sigma_g$) band system of nitrogen extends from 1200 Å to 2600 Å. It was first observed in emission by Lyman (1911) in a high voltage discharge lamp. It was later identified as a new band system by Birge and Hopfield (1928). Herzberg (1946) has shown the upper state must be ${}^1\Pi_g$, and the transition must be permitted by magnetic dipole selection rules. It has since been studied under high resolution by Loftus (1956) and Wilkinson and Mulliken (1957), who found the presence of quadrupole lines (S and O branches). The electric quadrupole contribution to the intensity was estimated to be about 13% of the total.

In 1965, McEwen measured the relative intensities of the bands of the Lyman-Birge-Hopfield (LBH) system. The results showed the electronic transition moment is a constant over the band system. Thus, the band strengths are directly proportional to the Franck-Condon factors for the band system. Franck-Condon factors for the LBH system were calculated

numerically, using Rydberg-Klein-Rees potential functions, by Benesch, Vanderslice, Tilford and Wilkinson (1966), and by Zare, Larsson and Berg (1965).

One of the first measurements of the lifetime of the LBH state was made by Lichten (1957). He used a collimated molecular beam, a small fraction of which had been excited by an electron beam. The excited molecules struck a moveable detector and ejected electrons. The number emitted varied as a function of distance. The distance function was used to calculate an average lifetime of the various states. The lifetime was 170 microseconds. In a similar experiment, Olmstead, Newton and Street (1965) obtained a lifetime of 120 microseconds.

More recently, Ching, Cook and Becker (1967) have used absorption measurements of N_2 to determine absorption band oscillator strengths, $f_{v''=0,\,v'}$ for the LBH system. Their results indicate a lifetime of approximately 37 microseconds. Holland (1969), in an electron beam excitation experiment, measured the total intensity of the LBH band system versus distance from an electron beam with a photometer and obtained a lifetime, uncorrected for slow cascade, of 80 microseconds.

Holland also measured excitation cross-sections from 100 eV to 2 keV for the LBH band system. Possible electronic transitions that might cascade to the LBH state and contribute to the

apparent cross-section are the $^1\Sigma_u^+$ and $^1\Pi_u^- \rightarrow$ a $^1\Pi_g^-$ transitions. Both are permitted electric dipole transitions.

Direct excitation of the $a^1\Pi_g$ transition by electrons, in an inelastic scattering experiment, has been observed by Lassettre and Krasnow (1964). By measuring the small angle inelastic scattering of electrons, the generalized oscillator strength for the LBH transition was determined at an accelerating voltage of 522 eV. Recently, Lassettre, Skerbele and Meyer (1966), and Lassettre, Skerbele, Dillion and Ross (1968) made a thorough study of excitation of the $a^1\Pi_g$ vibrational levels by observing at various scattering angles, the energy loss of a primary electron beam and found no change in the relative intensity of the vibrational levels of the $a^1\Pi_g$ state from 60 eV to 400 eV. Furthermore, the probabilities for direct excitation of the vibrational levels of the $a^1\Pi_g$ state were directly proportional to the (v¹,o) Franck-Condon factors.

A 'first principles' approach to the inelastic cross-section of the $a^1\Pi_g$ state of molecular nitrogen was a basic quantum mechanical calculation made by Rozsnyai (1967). He investigated inelastic electron scattering using the first Born approximation for homonuclear diatomic molecules. Two transitions in molecular nitrogen were investigated: the optically allowed $^1\Sigma_g \to ^1\Pi_u$ (Birge-Hopfield) transition, and the optically forbidden $^1\Sigma_g \to ^1\Pi_g$ (Lyman-Birge-Hopfield) transition. Both transitions involved a general type $\sigma \to \pi$ molecular orbital transition.

Another approach to inelastic cross-sections has been via the Born approximation at high energies and the modified Born approximation at low energies. Green and Barth (1965) and Stolarski et al. (1967) have calculated nitrogen excitation and ionization crosssections in an attempt to organize systematically inelastic crosssections for atmospheric computations. For example, they used the generalized oscillator strengths of Lassettre and Krasnow (1964) and phenomenological empirical formulas to obtain high energy crosssections for the LBH transition. It was interesting to note that their calculated cross-sections differed by about a factor of 2 at 522 eV. This might have been due to the necessity of extrapolating the generalized oscillator strengths to scattering angles beyond the $3\degree$ to $10.5\degree$ measurement of Lassettre and Krasnow. At high energy (100 eV or greater) their formulation of excitation cross-sections for permitted transitions, reducted to the familiar $1/\epsilon$ ln ϵ dependence of the Born approximation (where ϵ is the incident electron energy). However, any extrapolation to low energies by empirical formula can be a hazardous procedure, especially for a forbidden transition such as the $a^{1}\Pi_{\sigma}$ transition.

The low energy region is extremely important, since virtually all the photoelectron excitation of the atmospheric species in

the dayglow occurs between the threshold for the process and 60 eV. The photoelectrons are produced by solar XUV ionization of the atmospheric constituents. The ejected photoelectrons initially have a kinetic energy equal to the solar photon energy minus the ionization potential. Similarly in the aurora, the major part of the excitation of neutral species occurs in the low energy region by the secondary electrons. The secondary electrons are produced by ionization of the neutral species by the primary electrons in inelastic collisions, resulting in the ejection of electrons. For example, Green and Barth (1965) found that an incident primary auroral flux of electrons at 30 keV can produce 262 secondaries with an average secondary energy of 87.6 eV. This, coupled with the fact that inelastic cross-sections peak at about 2 to 4 times threshold and fall by factors of 3 to 50 at primary auroral electron energies, illustrate the importance of knowing low energy excitation crosssections.

In the last few years, the advances in instrument equipped rockets and satellites has led to direct observations of the aurora and the dayglow, and to measurements of the atmospheric composition and temperature. These data, combined with solar XUV flux measurements (Hinteregger, Hall and Schmidtke, 1964), electron energy distributions in the aurora (Westerlund, 1968 and Rees, 1969) and electron energy distributions in the dayglow (Dalgarno, McElroy and Stewart, 1969) make it possible to propose theories of the

electron excited dayglow and aurora. In both the dayglow and the aurora, the volume emission rate of the i-th transition of the k-th molecular species of number density \mathbf{n}_k may be written,

$$I_{ik}(z) = n_k(z) g_{ik}(z) \frac{\text{photons}}{\text{cm}^3 \text{ sec}}, \qquad (1.1)$$

where:

 I_{ik} is the volume emission rate at altitude z of the i-th transition of the k-th species,

is the emission rate factor-it directly relates the volume emission rate of an individual emission to the volume density of the emitter.

For excitation by photoelectrons or auroral electrons, \mathbf{g}_{ik} may be written as,

$$g_{ik}(z) = \int_{\epsilon}^{\infty} \Phi(\epsilon, z) Q_{ik}(\epsilon) d\epsilon \frac{\text{photons}}{\text{sec molecule}},$$
 (1.2)

where:

 $\epsilon_{\,\mathrm{T}}$ is the threshold energy for process i in eV,

- $\Phi(\epsilon,z)$ is the steady-state differential electron flux at altitude z and energy ϵ in units of electrons/sec cm 2 eV,
- Q_{ik}(ε) is the emission cross-section of the i-th transition of species k in units of cm². (The emission cross-section is the cross-section for excitation to a level or state uncorrected for cascading).

Thus, in order to make this calculation, to compare theory with rocket and satellite measurements of electron excited atmospheric phenomena quantitatively, and to determine the energy deposition of electrons into the atmosphere, there is a need to have laboratory measurements of emission cross-sections. The expression for g_{ik} is actually the number of excitations per molecule per second. Since there is negligible deactivation in the region of interest (120 km to 300 km) for atmospheric electron excited spectral emissions of N_2 in the vacuum ultraviolet, except for the Vegard-Kaplan transition, the expression for $\boldsymbol{\mathsf{g}}_{ik}$ is necessarily equal to the emission per molecule per second. In the case of the dayglow, the emission rate factor is a function of the solar zenith angle and the solar cycle, in addition to altitude, since the photoelectron flux is determined primarily by the intensity and the depth of penetration of the solar XUV radiation into the atmosphere. In the dayglow there are also other mechanisms for excitation of the atmospheric species, including resonant and fluorescent scattering, chemical and ionic reactions and photodissociative excitation.

Consider the ultraviolet aurora. The most prominent molecular emission features consist of the Lyman-Birge-Hopfield band system, with the most intense bands at 1325 $\mathring{\rm A}$, 1353 $\mathring{\rm A}$ and 1383 $\mathring{\rm A}$, the (4,0), (3,0) and (2,0) bands, respectively (Barth, 1968). The process is very simple,

$$N_2 + e \rightarrow N_2^* + e$$
 (direct excitation and cascade), (1.3)

followed by,

$$N_2^* \rightarrow N_2 + h \nu_{LBH} , \qquad (1.4)$$

Where N_2^{\star} refers to a nitrogen molecule, electronically excited to a particular vibrational energy level of the LBH state.

The calculation of the emission rate of the LBH transition is determined by Eqns. 1.1 and 1.2 and involves a knowledge of inelastic cross-sections of electrons for nitrogen molecules from threshold to about 10 keV.

Barth (1968) has made a calculation of the electron impact excitation of the auroral spectrum between 1200 Å and 1500 Å. By considering 4 keV monoenergetic electrons impinging on the atmosphere, and using empirical cross-sections, a comparison of theory and the atmospheric measurement of Fastie (1967) was made. The predicted intensities were higher than the rocket measured intensities by factors of 2 to 6.

At the time of Barth's calculation, it was assumed that the intense atomic nitrogen lines of the aurora, at 1200 Å, 1493 Å and 1743 Å, were caused by direct excitation of atomic nitrogen of atmospheric abundance of about 0.1%. The predicted intensities were too low by factors of 2 to 4. The reason for this discrepancy was that the excitation mechanism assumed is less important than a dissociative excitation mechanism, whose excitation cross-section was measured in this experiment. This was one of the most important results of the experiment.

The excitation mechanism is,

$$N_2 + e \rightarrow N^* + N + e$$
 (direct excitation + cascade), (1.5)

and

$$N_2 + e \rightarrow N^* + N^+ + 2e$$
, (1.6)

where N^* refers to electronically excited nitrogen. Eqn. 1.5 is a dissociative excitation process and Eqn. 1.6 is a dissociative ionization excitation process.

The emission mechanism is

$$N^* \rightarrow N + h\nu_{1200, 1493, \text{ or } 1743}$$
 (1.7)

In the atmosphere, the emission rate of these atomic nitrogen multiplets is determined by Eqns. 1.1 and 1.2, where the emission cross-section is the total dissociative excitation cross-section.

It is determined by adding the emission cross-section for dissociative excitation and the emission cross-section for dissociative ionization excitation for each transition.

In the dayglow, the atomic nitrogen lines emission are caused by photoelectrons. In addition, it is possible there may be a contribution by photodissociative excitation of molecular nitrogen. The cross-section for this process has not been measured. It is also of interest to point out that the dissociative excitation of molecular

nitrogen provides a minor source of atomic nitrogen atoms in the upper atmosphere in the region $120~\rm km$ to $250~\rm km$. The major source probably is dissociative recombination of $\rm N0^+$ with an electron. For the LBH bands, the primary excitation mechanism in the day-glow is photoelectron excitation.

1.2 Experimental Objectives.

It was intended to measure the apparent excitation crosssection of nitrogen for the Lyman-Birge-Hopfield electronic transition from 10 eV to 208 eV, thus, extending the cross-section measurement made by Holland from 100 eV to 2 keV. Crosssections are presented for the first seven vibrational levels of the a $^{1}\Pi_{g}$ state and for the total electronic transition of the a $^{1}\Pi_{g}$ state. It was expected that the higher levels would be weak, or absent, from predissociation (Herman and Herman, 1942). In addition, excitation functions were measured for each of the LBH vibronic transitions. This cross-section was the cross-section for excitation to the vibrational level multiplied by the branching ratio.

Furthermore, the apparent cross-section for dissociative excitation of nitrogen by electrons, leading to the atomic nitrogen multiplets at 1200 Å, 1493 Å and 1743 Å, were measured. It was ascertained that two processes contribute to the emission cross-section of the nitrogen lines. These processes were dissociative excitation and dissociative ionization excitation. In addition,

the contribution of the (3,3) LBH emission cross-section to the 1493 Å nitrogen line multiplet was determined.

It was established that all of these measurements were made in the range where the measured flux of radiation depended linearly on pressure and electron beam current.

It was necessary to design, construct and calibrate an electron beam excitation chamber, composed of electron gun, electron collector, vacuum system, electronics and vacuum ultraviolet spectrometer. The cross-section was determined by simultaneously monitoring the steady-state ultraviolet radiation (1200 $\mathring{\rm A}$ to 2000 $\mathring{\rm A}$), electron beam current, electron energy and nitrogen pressure. With molecular nitrogen in the flow regime (about 0.1 microns pressure) an electron beam was fired across a chamber, and excited, dissociated, or ionized the nitrogen molecules. The subsequent radiation from the excited nitrogen molecules and nitrogen atoms was monitored by the monochromator and photomultiplier tube. By assuming the excitation per unit length of the beam equaled the emission per unit length, and that all processes are linear with pressure and electron beam current, the emission cross-section was determined. Because of the long lifetime (80 microseconds) of the LBH state, account was made for the fraction of excited molecules that diffused out of the field of view.

The application of these measurements to the electron excited dayglow and aurora is discussed.

1.3 A Summary of the Presentation.

In Chapter II the design and construction of the electron beam excitation chamber is described. The necessity to build a large excitation chamber, using a monochromator with a fast optical system, capable of measuring the emission crosssections of the nitrogen multiplets, as well as the emission cross-section of the LBH transition, which is a magnetic dipole transition, prompted the design.

In Chapter III the calibration technique for the optical system is discussed. The calibration results for the separate parts of the optical system—the photomultiplier, the monochromator and the lithium fluoride window, are presented.

In Chapter IV the theory of the electron beam excitation of N_2 is discussed. The various reactions that occur when an electron beam is incident on a neutral nitrogen gas at low pressure are summarized. In addition, the geometrical and physical factors determining the fraction of the emitted radiation from the excited nitrogen atoms and molecules detected are discussed.

In Chapter V the experimental results are presented.

First, the preliminary measurements that determine the range of electron beam currents and molecular nitrogen pressures, for

which the measured flux of radiation is linear in these two parameters, are summarized. Secondly, the observational technique and experimentally derived emission cross-sections as a function of energy are presented.

In Chapter VI the results are applied to the atmosphere.

Emission rate factors are determined for the LBH band system

and the atomic nitrogen multiplets in the electron excited dayglow as a function of altitude, and in the auroral oval at 150 km.

CHAPTER II

INSTRUMENTATION

2.1 Introduction

The instrumentation for this experiment consisted basically of a source, the electron beam excitation chamber, and a detector, the monochromator with photomultiplier. Each was designed according to the specific needs of this particular experimental problem. It was necessary to build the electron beam chamber so that the characteristic lengths in the chamber were larger than the distance a nitrogen molecule, excited to the Lyman-Birge-Hopfield state, would travel before radiating. With the lifetime of the order of 80 microseconds, and a gas temperature of 293 °K, an excited molecule could travel about two inches before radiating. Since the interaction of excited molecules with walls was unknown, walls had to be placed out of the interaction region. This requirement was met by providing a six-inch electron beam in a cylindrical chamber eight inches in diameter. The atomic nitrogen lines, being permitted electric dipole transitions, did not have this problem but could be studied with this particular design. The ultraviolet radiation of the Lyman-Birge-Hopfield band system was confined to a glow region around the beam, whose intensity fell off a little faster

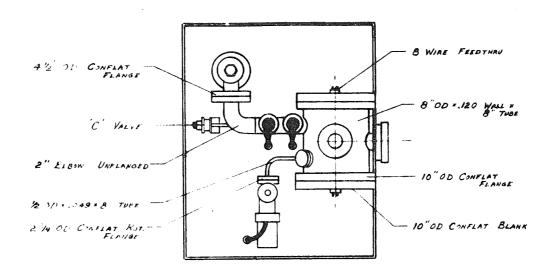

than 1/r, where r is the distance from the electron beam. See the calculation of the glow distribution in Chapter IV. It was obvious from these considerations that it was desirable to have a fast optical system of very low f number in order to collect as much of the radiation as possible. For this reason, it was decided to use the McPherson 218 monochromator of f/5.3. Furthermore, studies in the vacuum ultraviolet required the use of vacuum systems so that the monochromator could be kept at very low pressure. This was due to the fact that air is very opaque to radiation in the wavelength region less than 2000 Å.

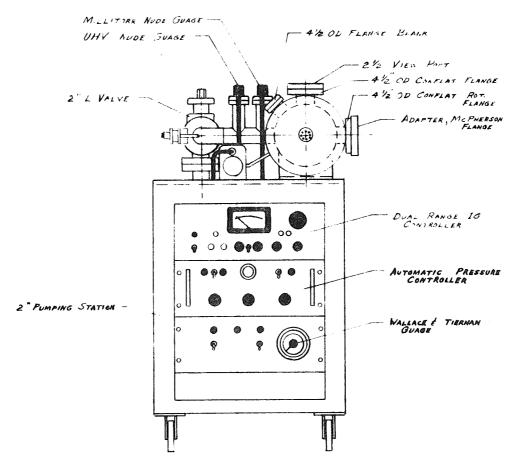

2.2 The Electron Beam Excitation Chamber and Vacuum System.

The electron beam excitation chamber was cylindrically shaped and made of stainless steel. It is shown in Figures 2.1 and 2.2. A complete description of the excitation chamber is given in Appendix A.

2.3 The Vacuum System.

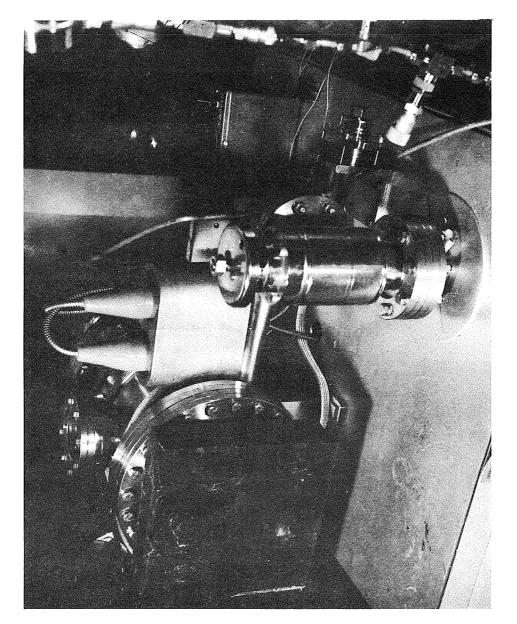

The vacuum system is displayed in Figure 2.3. It consists essentially of a liquid nitrogen baffled diffusion pump and forepump. The ultimate pressure obtainable in the system was 8×10^{-8} torr without the electron gun in operation and 1×10^{-7} torr with the gun in operation. The chamber was submitted to a mild bakeout before each experimental use by a heating coil.

ELECTRON BEAM EXCITATION CHAMBER & PUMPING STATION

FIGURE 2.1

THE ELECTRON BEAM EXCITATION CHAMBER FIG. 2.2

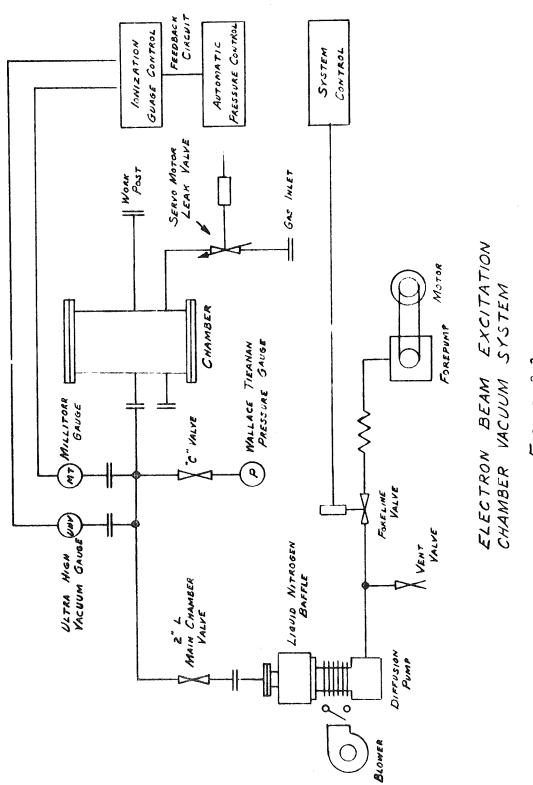

FIGURE 2.3

2.3.1 The Pumping System.

The pumping system was a Granville Phillips 2 inch, series 225, ultra-high vacuum pumping station. It consisted of a 2 inch diffusion pump and mechanical fore-pump. The diffusion pump was air cooled and had a cyrosorb cold trap to prevent any back-streaming of oil. The trap was automatically filled by a Delta Engineering automatic liquid nitrogen controller.

2.3.2 The Gate Valve.

The gate valve was a 2 inch gold seal ultra-high vacuum valve. It was manually operated and had a maximum conductance of 60 liters/sec and a minimum conductance of 10^{-13} liters/sec.

2.3.3 Pressure Measuring Instrumentation.

The pressure in the chamber was monitored with a dual range ionization gauge and control unit. For high pressure, a millitorr nude gauge read from 1 x 10^{-5} torr to 1 torr. For low pressure, a Varian ultra-high vacuum gauge read from 2 x 10^{-11} torr to 10^{-3} torr.

During the experiment the millitorr gauge was used to monitor the pressure. It was operated at very low emission currents (11 microamps) and produced electron paths of very short lengths. The electrons collided with the gas molecules and produced ions, which were collected and indicated the pressure. The millitorr gauge was calibrated for nitrogen gas molecules by Ball Brothers

Research Corporation of Boulder, Colorado, using a mercury McLeod gauge; absolute pressures were given at seven points between 10⁻⁵ torr and 10⁻¹ torr. The effect of thermal transpiration did not enter into the pressure measurement. The instrument was calibrated with the same geometrical configuration of gauge and chamber as used in the experiment. The McLeod gauge measured the pressure in the chamber and determined the absolute pressure calibration for the millitorr gauge. Even though the nipple that contained the millitorr gauge became approximately 40°C warmer than the gas in the chamber, the effect of thermal transpiration was not transferred into the measurement. It was found necessary to magnetically shield the ionization gauges from the magnetic plates used to guide the electron beam. The magnetic shield was not used in the calibration, since the imposed magnetic field of the magnetic plates was not present. Tests were run to insure that the pressure readings were the same under conditions of no imposed magnetic field and no magnetic shield to conditions of an imposed magnetic field and a magnetic shield. The shield was manufactured by Perfection Mica Corporation of Chicago, Illinois. The magnetic shield was made of conetic material, 0.060 inches thick and could attenuate the 160 gauss field to less than 1 gauss inside the gauge. Without the shield, pressure readings were 30% too high under conditions of the imposed magnetic field of the magnetic plates.

2.3.4 Automatic Pressure Controller.

An automatic pressure controller, manufactured by

Granville Phillips Corporation, was used for precise control of the

gas pressure in the chamber. The automatic pressure controller

(APC) was an electro-mechanical instrument designed to regulate

automatically the gas pressure in a system. When combined with

a pressure transducer, the APC could accurately maintain the gas

pressure by automatically and continuously admitting the gas to

a dynamic system to compensate for gas being removed by pumps.

The millitorr gauge output (0 to 100 millivolts) served as the trans
ducer. The APC constantly monitored the signal from the ionization

gauge and subtracted it from the control point desired; thus, pro
viding an error signal to either open, close, or maintain the valve

opening in the leak valve between the chamber and the gas source.

2.4 The Electron Gun and Electron Collector.

2.4.1 The Electron Gun.

The electron gun used in this experiment is shown in Figure 2.4. It was provided by Superior Electronics Corporation of Clifton, New Jersey, who modified their SE-63M gun design for use in this experiment. The electrodes were made of stainless steel, .005 inches thick and 5/8 inch diameter. The electrodes were rigidly maintained in place by an insulated ceramic mounting rod. The

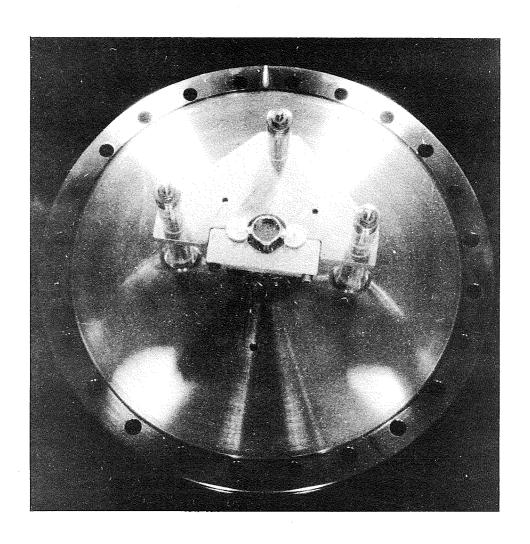

FIG. 2.4 THE ELECTRON GUN

entire assembly was fastened to a stainless steel plate, which kept the electron gun apertures on the center line of the chamber. The coaxially mounted electrodes consisted of an anode, a current control grid, and the cathode. The holes in the electrodes were 1 mm in diameter. Each electrode was spaced about .008 inches apart. Two types of cathodes were used. One was an indirectly heated nickel oxide coated cathode, and the other was a directly heated thoriated tungsten cathode. The nickel oxide coated cathode had to be activated in a high vacuum. During the exhaust pumping of the electron gun, it was necessary to employ a schedule of various applied voltages to the heater of the tube and the electrodes. The purpose of applying this power was to heat the cathode through a cycle which accomplishes the following items:

- (1) Chemically decompose the carbonates to oxides with the release of ${\rm CO}_2$.
- (2) Start a reaction between the oxides and the materials in the cathode base nickel to reduce the oxides and create free alkaline earch materials (barium, strontium, and calcium). It is the availability of the first two elements which causes the phenomenon of electron emission.

While the above processes were carried out, the vacuum system was pumped rapidly enough to remove the by-products of the reaction, as well as outgassing material. The voltage on the heater was gradually increased until a rapid evolution of gases

was noted by a sharp increase in pressure. This was the so-called activation region and the voltage increments thence must be applied slowly enough to maintain a high vacuum (5 x 10^{-6} torr or less). After passing through the activation region, the heater voltage was returned to between 6.5 and 7 volts. Voltages were put on the control grids to give the electron beam the desired energy and current.

The measurement of cross-section for energies less than 30 eV was made with the oxide coated cathode. It provided ample electron emission of up to 1 ma. In the experiment, electron beam currents from 25 microamps to 250 microamps were used.

The tungsten gun was used for pressure versus intensity measurements and high energy measurements (30 eV to 208 eV). It did not need to be activated and stabilized readily to pressure changes during the intensity versus pressure measurements. Both types of guns had long lifetimes of 100 hours or more. The electron gun was operated with the anode grounded and the chamber grounded so as to make the interaction region field free. The beam was collimated by a 160 gauss magnetic field provided by two large magnetic plates made of barium ferrite, provided by Bux Shrader Company of Los Angeles. The plates were 8 1/2 inches square and 2 1/4 inches thick and 12 inches apart. The ceramic magnets were epoxy encapsulated for rigidity and epoxied to a

hot rolled steel plate for support on the end flange of the chamber. Most of the fringing tendency of the field was contained by a horse-shoe arrangement of hot rolled steel, 1/4 inch thick and 3 inches wide. The top of the horseshoe was 24 inches above the chamber. The field lines were intended to be straight at the center of the chamber and magnet. There was no measurable spreading or curving of the 1 mm in diameter beam across the 6 inch path length, as observed by the blue light of the permitted transition of the first negative bands of N_2^+ .

2.4.2 The Electron Beam Collector Cup.

The electron beam collector cup was made of stainless steel and OFHC copper. It consisted of two parts—a cylindrical bias plate and a collector cone. The cylindrical bias plate was 2 1/2 inches long and 1/2 inch in diameter. It is desirable to have a large length to diameter ratio. At the end of the cylinder was attached a cone of 90° apex angle and a 1/2 inch depth. The cylinder was normally held at +30v with respect to the grounded anode and grounded excitation chamber. It served to refocus the beam to the center of the cone where the electrons were trapped by the cone which had a +100v potential. The primary electrons were trapped in the cone by being forced to make a number of collisions with the surface of the cone, if they were reflected. The positive potentials also served to collect any ejected

secondaries. When the electrons collided with the copper cone, they penetrated the surface of the metal, the depth of penetration depending on the primary energy. As the result of interactions with the nuclei and electrons in the target material, the electrons lost energy. Some secondaries were ejected from the target by the ionization produced by the primaries. Furthermore, some primary electrons were inelastically scattered back to the surface with lower energy. If either the scattered primaries or ejected secondaries had enough energy to cross the potential barrier of the metal, they may have escaped back into the chamber. Thus, the main reason for the cone was to cause many collisions with the surface and to produce few electrons with enough energy to escape. At very low energies (up to 20 eV) and very high energies (75 eV and greater), few escaping secondaries were ejected. At very low primary energies, the energy of the secondaries was less than the work function of the target. At very high primary energies, the secondaries were produced deep within the target and lost a great deal of energy in collisions. Finally, there were the elastically scattered or reflected primaries (as much as 20% reflection coefficient per collision with a copper surface at 300 eV per collision, [McDaniel, 1964]), the cone caused these reflected primaries to make a number of collisions and minimized any escape into the chamber.

A grounded plate with a hole 1/2 inch in diameter was placed in front of the collector to minimize any field leakage into the interaction chamber. The high charge density of the electron beam also prevented any significant field penetration into the beam.

2.4.3 The Electronics for the Electron Gun and Collector.

The electronics schematic for the electron gun and collector is shown in Figure 2.5.

The dc power supplies were ABC model Kepco-power supplies regulated to 0.05% and with a stability of 3 millivolts. The voltages were monitored with calibrated Hewlett-Packard dc vacuum tube voltmeters, model 412A. The electron beam current was monitored by a Keithly model 602 electrometer. Both the power supplies and the electrometer were capable of operating off ground, since the dc terminals were isolated from the chasis. One leg of the filament was tied to the cathode, which was at a negative potential with respect to the anode. The filament was thus operated at a negative potential close to that of the cathode, preventing any discharge between filament and cathode. The current control grid was operated at a few volts above or below the cathode, depending on the electron beam current desired, which was usually between 50 and 250 microamps. The current going to the anode was about 1 microamp, for accelerating voltages greater than 25 eV, and was of the order of 10 microamps for operating voltages less than 25 eV. This current was due to the mode of emission of the electron gun.

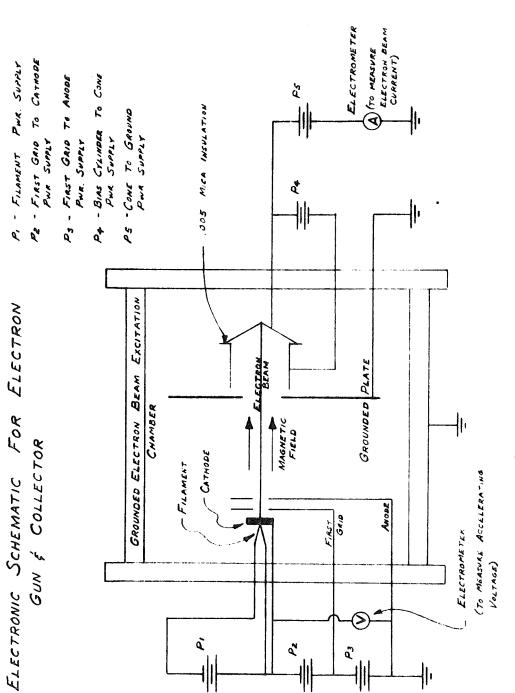

FIGURE 2.5

For high accelerating voltages the emission was temperature limited, since the voltages were strong enough to pull off all electrons leaving the cathode. At low voltages, it was space charge limited, since the accelerating voltages were not strong enough to pull off all the electrons. The current going to the grounded plate was less than 1 microamp. Furthermore, it was found that if the collector voltage is decreased below 50 volts, a substantial number of electrons were reflected from the collector as determined by an increase in anode current and a corresponding decrease in collector current. This phenomenon serves as a test for electron collection, since above 50 volts collector cone potential, no change in either collector current or anode current was noted. The anode current can even be 1 or 2 microamps positive corresponding to a small positive ion current.

2.5 The Monochromator.

2.5.1 Description of the Monochromator.

The monochromator used was a McPherson 0.3 meter, f/5.3, plane grating, capable of vacuum or atmospheric scanning. It was designed to operate in the wavelength range of 1050 Å to 16 microns by interchanging snap-in gratings and photomultiplier tubes. It is shown in Figure 2.6. The wavelength range from 1200 Å to 2000 Å was investigated by evacuating the spectrometer with an oil diffusion pump and liquid nitrogen baffle. The optical

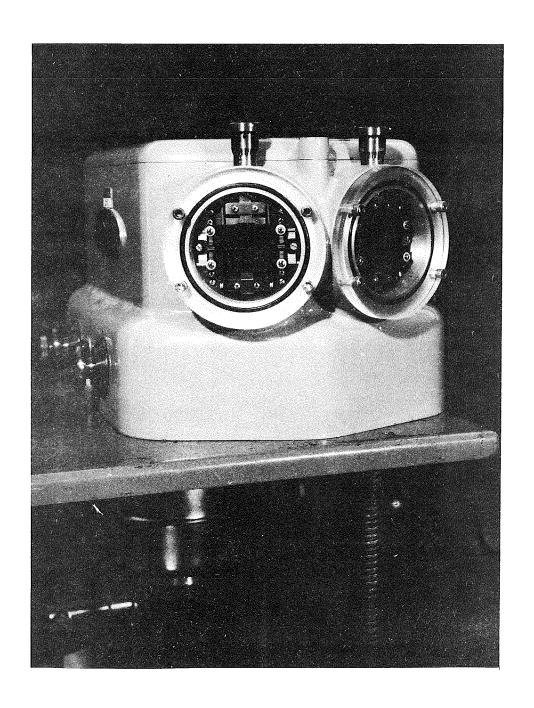

FIG. 2.6 THE McPHERSON 218 MONOCHROMATOR

system was a standard Czerny-Turner mount. It consisted of two concave mirrors and a plane diffraction grating. The monochromatic action was accomplished by a rotation of the plane grating about its center. With this optical system, off-axis aberrations, produced by reflection from the first concave mirror, were cancelled by reflection from the second concave mirror. It seems the limit of resolution was determined by imperfections in the grating and not by aberrations of the optical system. The combination of aluminum and magnesium fluoride coatings on mirrors and grating gave excellent reflecting power down to 1200 Å. The coating of $\operatorname{Mg} \, F_2$ on a freshly aluminized surface has been shown to greatly enhance the reflectance of the surface at short wavelengths by interference effects. The grating used in the experiment was a 2400 lines per millimeter replica grating. The grating was blazed at 1500 A and its ruled area was 52 mm x 52 mm. The 2 inch aperature stop around the mirrors gave an effective focal ratio of f/5.3. The slit was set at a height of 4 mm. The slit width employed for the spectral scans was normally 200 microns. In addition, scans were made at a slit width of 100 microns for high resolution studies of overlapping bands and at a slit width of 400 microns for study of weak bands. The grating equation for this optical system is

$$n \lambda = 2 d \sin \theta \cos \alpha , \qquad (2.1)$$

where:

- d is the grating (groove) separation,
- lpha is the ray separation half-angle and is equal to 14 $^{\circ}$ for this monochromator,
- θ is the grating shaft angle.

The dispersion or plate factor for the instrument, using the 2400 lines/mm grating, was $d\lambda/dl=13.9\,\text{Å/mm}$. This equation gave a dispersion of 2.78 Å at a 200 micron slit width. The resolving power and dispersion are closely related quantities. Since the instrumental resolving power was much less than 2.78 Å, the monochromator can resolve two wavelengths of about 3 Å separation. Since most of the spectral scans were made between $1200\,\text{Å}$ and $2000\,\text{Å}$ at a speed of $50\,\text{Å/min.}$, the entire spectrum was recorded in 16 minutes. This time was short enough that the electron beam excitation source remained constant to within a few per cent. During the scan the electron beam current and nitrogen gas pressure of the source were recorded in 30 second intervals.

The electron beam excitation chamber and monochromator were separated by a lithium fluoride window with a vacuum tight seal. This arrangement was used for two reasons. First, it was calculated that the 2 inch diffusion pump of the monochromator did not have a fast enough pumping speed to keep an order of magnitude pressure differential between the excitation chamber and the monochromator without the lithium fluoride window. It was

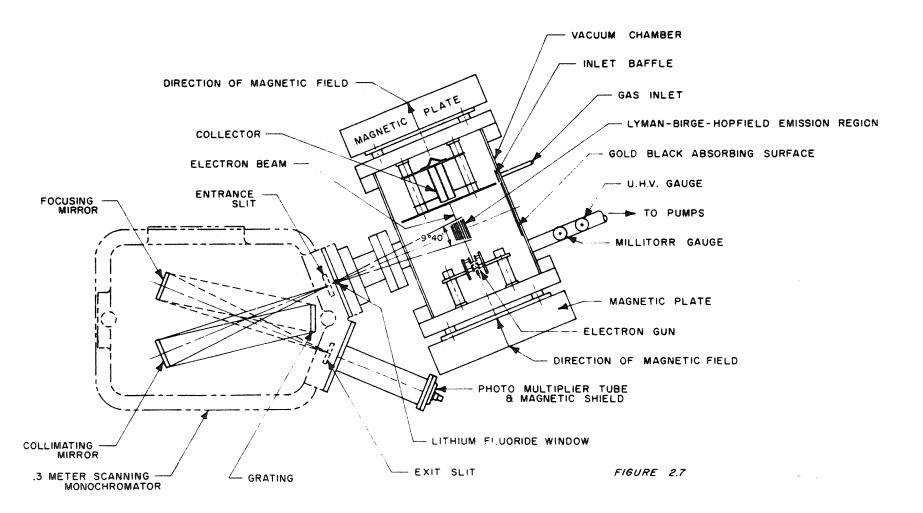

desirable to keep the photomultiplier tube well away from its arcing region, which begins at about 10^{-3} torr pressure. Second, for safety reasons in case of a power failure, a sudden rise of pressure in the excitation chamber, which was not equipped with automatic fail-safe valves, would not be transmitted to the monochromator. The lithium fluoride window was 2 mm thick and 1 inch in diameter. The top view of the electron beam chamber and monochromator is shown in Figure 2.7.

The distance from the entrance slit of the monochromator to the electron beam was 9 13/16 inches. The advantage of this fast optical system was its large field of view--9°40'. This enabled the photomultiplier to detect radiation at a distance of 2.11 mm from the beam. Since the Lyman-Birge-Hopfield band system has a lifetime of about 80 microseconds, it appeared as a diffuse glow, strongest at the electron beam, and fell off in intensity a little faster than 1/r, where r is the distance from the beam. (See Chapter IV for the calculation of glow intensity as a function of distance from the electron beam). The detector could see about 75% of the LBH emission and, of course, all of the permitted atomic nitrogen line emission.

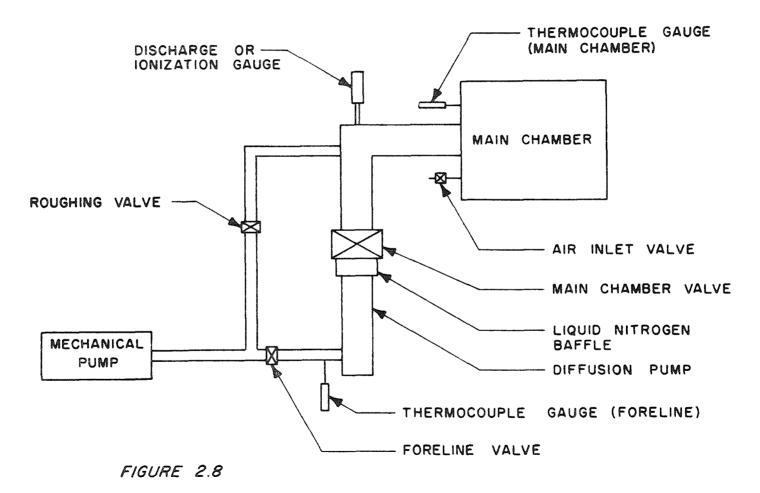

2.5.2 Vacuum System of the McPherson 218 Monochromator.

The vacuum system is illustrated in Figure 2.8. The vacuum system consisted of a Welch forepump, a 2 inch Consolidated Vacuum Corporation diffusion pump, a Granville Phillips

TOP VIEW OF ELECTRON BEAM EXCITATION EXPERIMENT

VACUUM SYSTEM SCHEMATIC FOR McPHERSON 218 MONOCHROMATOR

liquid nitrogen baffle, and a Delta Engineering automatic liquid nitrogen controller. The pressure in the chamber was monitored by a thermocouple gauge at high pressures and an ionization gauge at low pressures. The monochromator had a valve for admitting air to bring the system to atmosphere. The valves were all automatically activated by push button controls on the main control panel. The vacuum system was protected from overheating by a mercoid control, which would close the main chamber valve and diffusion pump, if the diffusion pump became too hot. The monochromator was made of aluminum. The ultimate pressure in the monochromator was designed for 1×10^{-5} torr. Lower pressures could not be reached, and were not needed, since 1×10^{-5} torr pressure was low enough for vacuum ultraviolet measurements, i.e., the optical depth is much less than one in the ultraviolet for the transitions of interest.

2.5.3 The Photomultiplier Tube.

The detector used in this experiment was an 18 stage, end on, lithium fluoride window tube with a 10 mm diameter, semitransparent cesium iodide photocathode. The response of this tube extended from 1050 Å, the cut-off of the cleaved lithium fluoride window, to the photocathode threshold at 2500 Å. Thermionic emission of the high work function photocathode was extremely small, resulting in exceptionally low dark currents. Typical dark

currents were .1 and .2 picoamperes a half-hour after the 3000V high voltage was turned on. The peak response of this particular photomultiplier was at 1550 Å, falling to 40% of this value at 1200 \mathring{A} and 1880 \mathring{A} . The q_λ' g factor (quantum efficienty times gain for the photomultiplier) at 1216 Å, with 3000 volts across the photomultiplier, was 7.54×10^3 electrons/photons. The photosensitive cathode was located 11/16 inch away from the exit slit of the monochromator. The slit height was 4 mm, giving a 6.8 mm image height of the photocathode. The photomultiplier, which was physically very close (about 3 inches at closest approach) to the magnetic plates used to guide the electron beam, was shielded by a magnetic shield made especially for reducing a 160 gauss field to less than 1 gauss inside the tube. This accessory was necessary in order not to perturb the path of the electrons from dynode to dynode. The photomultiplier shield was made specifically for this experiment by the Magnetic Shield Division of Perfection Mica Corporation of Bensonville, Illinois. The material for the magnetic shield was 0.060 inch thick conetic material, high permeability, low reluctance material that shunted the magnetic field around the surface and reduced the magnetic field at the photocathode by 50 db. It was a rolled cylinder, heli-arc welded and annealed at 2000°F.

2.5.4 Electronics for the Detection System.

The high voltage supply for the photomultiplier was a Fluke Engineering power supply, model 408A, which was periodically calibrated. It was regulated to within 0.01% and ripple was maintained at less than 4 m.v.R.M.S. The supply was run with the negative terminal at -3000v and the positive terminal at ground. All cables were shielded. The output of the photomultiplier went to a Kiethly model 417 picoammeter equipped with damping controls and suppression current offsets to offset the dark current. Typical currents from the stronger LBH bands were of the order of 0.5 \times 10⁻¹¹ amps. The three scales used for the experiment were $.3 \times 10^{-11}$ amps, 1×10^{-11} amps and 3×10^{-11} amps full-scale readings. The output of the picoammeter went to a Brush recorder, Mark 280, of the Clevite Corporation of Cleveland, Ohio. The output was run at 50 mv/line and at 1 mm/sec chart speed. The picoammeter and Brush recorder combination were periodically calibrated with a picoampere source. The corrections applied were less than 1%. During the calibration the scales used were the 10^{-8} and 10^{-9} amps, full-scale ranges of the picoammeter. These scales were also calibrated with the picoampere source. The corrections applied were less than 3%. The damping control on the picoammeter was used to filter out photomultiplier noise. The bucking current supply of the picoammeter was used to offset the

photomultiplier dark current. The value of dark current stabilized to 0.1×10^{-12} amps, a half-hour after the high voltage was turned on. The chart speed of 1 mm/sec, used in conjunction with the 50 A/min drum speed of the monochromator, resulted in an output that separated the bands for convenient integration to determine the resultant intensity. Thus, the spectrum from 1200 Å to 2000 Å was displayed on a chart 42 inches long. The amplifier setting of 50 mv/line on the Brush recorder gave sizable peak heights of about 3 inches above the zero setting on the recording. The fullscale output of the picoammeter was 3 volts. The accuracy of the picoammeter is $\pm 3\%$ on the 3×10^{-9} to 1×10^{-13} ampere ranges. Fast response resulted from a circuit using a high gain dc amplifier and a critically damped feedback network, which conveniently adjusted the response speed. This helped achieve a balance of response speed and noise, thus minimizing the effect of 60 c.p.s. and other external noise pick-up. Tests were run to ensure that the area under each band was independent of the damping control setting. Zero drift was less than 1% of full-scale per 8 hours. The electronics schematic for the detection system is shown in Figure 2.9. The electronic rack is shown in Figure 2.10.

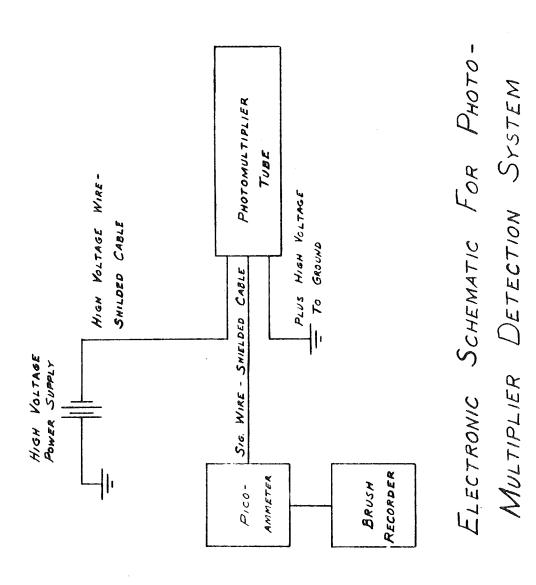

FIGURE 2.9

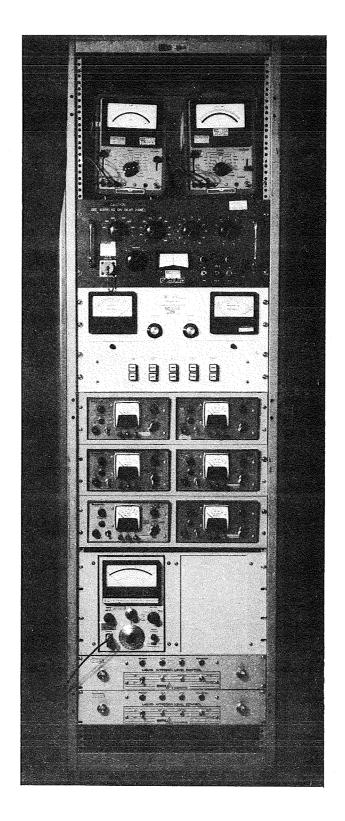

FIG. 2.10 THE ELECTRONIC RACK

CHAPTER III

CALIBRATION

3.1 Introduction

In order to determine the absolute cross-section in an electron beam excitation experiment by optical measurements, it is necessary to know the absolute response of the detector and monochromator as a function of wavelength. Such a determination is conceptually straightforward in the visible and near ultraviolet regions where black body radiation can be used as a radiation standard. In the vacuum ultraviolet there is no satisfactory intensity standard to determine the relationship between the response of the spectrometer and the true intensity distribution of the radiation incident upon the spectrometer.

Before discussing the calibration techniques employed in the present study, it is useful to review the individual parameters which determined the overall absolute wavelength response of the spectrometer and detector. The parameters are:

- The transmission of the lithium fluoride window between the spectrometer and electron beam chamber.
- The efficiency of the monochromator-grating and two mirrors.

3) The photomultiplier response.

To measure the absolute intensity of radiation at any wavelength, it is necessary to have a detector whose response is known in absolute units. This detector must be calibrated against a standard source, such as a black body source, or it must be an absolute detector, whose response to the radiant intensity can be calculated. The emission of black body furnaces are confined to wavelengths greater than 2700 Å, and thus, cannot serve as a standard source in the wavelength range of interest, 1200 Å - 2000 Å. According to Samson (1967) the most accurate and reproducible method of measuring absolute intensities is based on the photoionization of a suitable gas. The photoionization yield of a gas is defined as the number of ions produced per photon absorbed. Thus if an ionization chamber is filled with an appropriate gas until all of the incident photons are absorbed, the number of photons per second incident times the photoionization yield is equal to the ion current produced. Of particular interest is the yield of NO at Lyman-alpha (1215.7 Å), which has been measured by Watanabe et al. (1953) and Watanabe (Samson, 1967, P. 250, Table 7.4) to be 81%. Samson (1967) has a complete review of recent measurements of photoionization efficiencies. The value for the yield of NO has been used to determine the intensity of hydrogen Lymanalpha emitted from the sun by using NO ionization chambers in

rockets and satellites. The photoionization yield technique is used for measuring detector response by comparing the response of an unknown detector to an ionization chamber output for the same input radiation from a discharge lamp. This method, however, cannot be used directly to determine monochromator response. Thus, it is not an adequate means of calibrating a complete optical instrument. Moreover, it is limited to short wavelengths above the ionization potential—for nitric oxide the useful range is up to only 1343 Å.

It was necessary to do the calibration, piecemeal, by calibrating the detector, the monochromator and lithium fluoride window in separate calibrations. Finally, by multiplying the resulting calibration factors together, it was possible to get the overall response of the instrument. The lithium fluoride window and the monochromator were calibrated by measuring both the input radiation to each from a discharge lamp at many wavelengths. The detector, a 541 G EMR photomultiplier, was calibrated absolutely at Lyman-alpha using a hydrogen d.c. discharge lamp with a nitric oxide cell and relative to Lyman-alpha at all other wavelengths of interest (1200 Å - 2000 Å) by a sodium salicylate calibration.

Sodium salicylate is a fluorescent material. The fluorescent efficiency of a freshly prepared layer is a constant between 1400 Å and 2000 Å and slightly less from 1200 Å to 1400 Å (Knapp and

Smith, 1964). By comparing the response of the unknown detector to a detector with a sodium salicylate layer for the same incident radiation, it was possible to obtain a relative wavelength calibration for the photomultiplier.

All calibrations were made on the McPherson 225 monochromator. It was an f/10 by f/20 system. Using this instrument had many advantages. The 225 had butterfly slits on both the entrance and exit slits with its own roughing pump. This set-up enabled one to isolate the exit slit from the main chamber for a quick change of detectors in the photomultiplier calibration. The 225 also had a faster pump-down time than the 218, since it had a 4 inch diffusion pump and a higher ultimate vacuum of about 5 x 10^{-7} torr. The source in the relative calibration measurements was a Hinteregger d.c. discharge lamp operated at 400 microns pressure with nitrogen as the gas source. The Hinteregger source needed about a one hour warm-up for stability in reproducing spectral lines. Thus, calibration points were obtained at the same wavelengths as measured in the experiment. The discharge lamp formed a rich spectrum between 1200 Å and 2000 Å--filled with the Lyman-Birge-Hopfield and Birge-Hopfield band systems and with many atomic nitrogen lines. The discharge lamp was separated from the spectrometer by a lithium fluoride window.

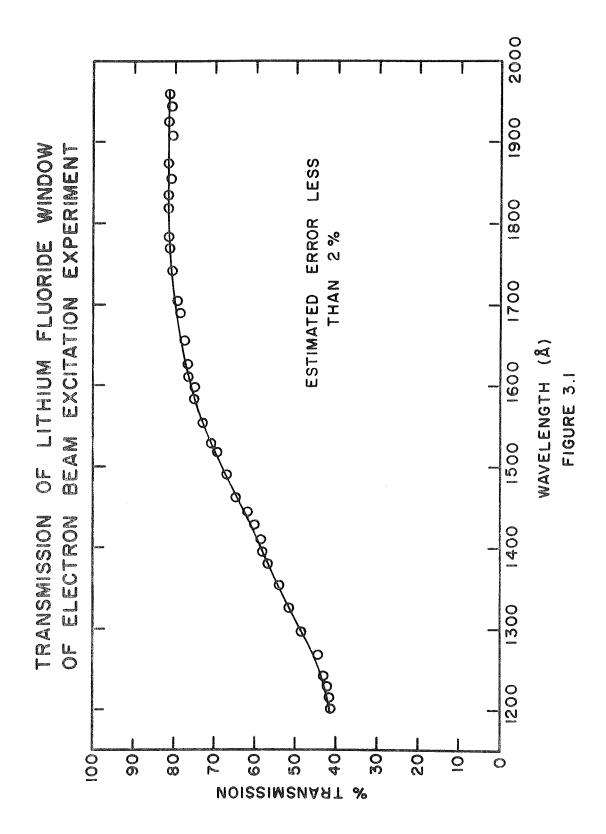

3.2 Transmission of the Lithium Fluoride Window.

The transmission of the lithium fluoride window is shown in Figure 3.1. This was the transmission characteristic of the lithium fluoride window used in the electron beam experiment. The window was 2 mm thick and 1 inch in diameter. The detector in the calibration was a 541 F EMR photomultiplier, since it had a very good long wavelength response. The window was mounted on a filter wheel with one blank opening and one opening for the lithium window. The filter wheel was placed between the photomultiplier and the exit slit. By rotating the window in and out of the monochromatic radiation supplied by the spectrometer, the transmission was obtained at about 50 wavelengths between 1200 A and 2000 Å. Due to the low intensity of the ultraviolet radiation in the electron beam chamber, there was no indicated change in the transmission of the window such as caused by color centers. Both sides of the window were always maintained at high vacuum, preventing any contamination.

3.3 Relative Calibration of the Photomultiplier.

The 541 G-08-18 EMR photomultiplier was calibrated between 1200 Å and 2000 Å by direct comparison with a 541 A EMR tube, which had a sodium salicylate fluorescent filter in front.

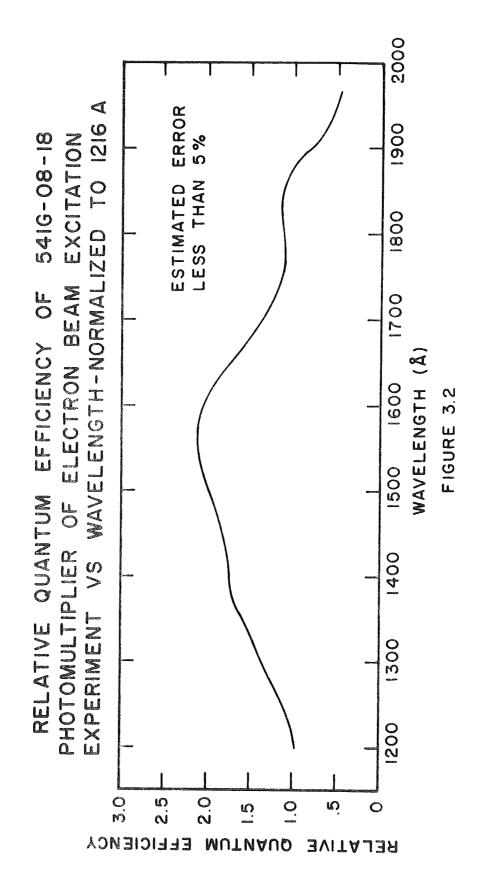

The relative quantum efficiency of the 541 G photomultiplier used

in the experiment is shown in Figure 3.2. The results were normalized to 1216 Å, since it was at this wavelength the absolute calibration of the photomultiplier was made.

Sodium salicylate had the important property of having a high fluorescent efficiency between 850 Å and 2000 Å. It has been shown (Knapp and Smith, 1964) that the quantum efficiency of sodium salicylate was a constant from 1420 Å to 1700 Å to within 3%. These authors gave relative quantum efficiencies from 1200 Å to 1700 Å. This data was used in the calibration to normalize the data to 1216 Å, thus putting the relative calibration on the same scale.

Sodium salicylate is a very fine crystalline power. It readily dissolved in ethyl alcohol. After obtaining a saturated solution, it was sprayed onto a quartz slide using an atomizer. The surface densities used were 2, 3 and 4 mg/cm², in three separate calibrations. The response of sodium salicylate peaks at a surface density of 1 mg/cm² and falls off slowly with increasing thickness. The results of the separate calibrations were the same to within 3%. The averaged results are displayed in Figure 3.2. The sodium salicylate filters were used within an hour after preparation. The fluorescence occurred in a wavelength region centered about 4400 Å and matched the wavelength sensitivity of the 541 A tube. The filter was placed in front of the 541 A

photomultiplier and a spectral scan was made from 1200 Å to 2000 Å. Then a sequential scan was made with the 541 G tube. This procedure was repeated. A ratio was made of the intensity of a spectral line with the G tube to the intensity of a line with the A tube. This procedure was repeated with about 50 lines. The results were normalized to the 1216 Å line calculation and included the quantum efficiency corrections for sodium salicylate of Knapp and Smith (1964). The peak response of the photomultiplier was at 1550 Å. The response fell to 1/2 of the peak at about 1220 Å and 1875 Å. Care was taken to illuminate the same portion of the photocathode as used in the experiment. This precaution was necessary, since the quantum efficiency of photomultipliers varies across the surface of the photocathode, especially at long wavelengths.

3.4 Absolute Calibration of the Photomultiplier at 1216 A.

The absolute calibration of the 541 G EMR photomultiplier was made at 1216 $\mathring{\text{A}}$ with a NO ion chamber. The basic principle involved was that the number of ions produced in an ionization chamber depends on the number of photons absorbed by the gas and on the photoionization yield of the gas. The number of photons absorbed by a gas is given by the Lambert-Beer law as

Number of photons absorbed =
$$I(1-e^{-\sigma nL})$$
 (3.1)

where:

- I is the intensity of the radiation in photons per second entering the chamber,
- L is the length of the chamber,
- n is the number of molecules per cm^3 ,
- σ is the total absorption cross-section of the gas at 1216 $\mathring{\text{A}}$,
- T is the transmittance of the window material—lithium fluoride in this case,
- I_{Ω} is the intensity of the incident radiation, thus,

$$I = T I_{O} , \qquad (3.2)$$

and the number of primary ions produced per second is given by

$$\frac{i}{e} = T I_O \gamma (1 - e^{-\sigma nL}) , \qquad (3.3)$$

where γ is the photoionization yield and i is the ion current.

If the optical depth, τ , is much greater than 1, that is, if

$$\tau = \sigma nL \gg 1 \tag{3.4}$$

then,

$$\frac{i}{e} = T I_O \gamma . ag{3.5}$$

By quickly replacing the NO chamber on the exit slit with the 541 G photomultiplier and measuring the current generated in the tube, a relationship for the response of the tube at 1216 $\rm \mathring{A}$ was obtained using

$$I_{O} = \frac{\ell_{pmt}}{e \, q'_{\lambda=1216} \, g} \,,$$
 (3.6)

where:

 $\ell_{\,\mathrm{pmt}}$ is the output current of the photomultiplier,

q' is the quantum of efficiency of the photo- λ =1216 mutiplier, at 1216 Å,

g is the gain of the photomultiplier.

Thus,

$$q'_{\lambda=1216} g = \frac{T\gamma \ell_{pmt}}{i}$$
 (3.7)

When all the ions are collected, Eqn. (3.5) represents the total current in the ion chamber. The ion current saturates at a few volts and then stays constant for nearly 150 volts until ion multiplication begins. Ion multiplication sets in when an electron acquires enough energy to cause secondary multiplication. The voltage used in the calibration was 23 volts and the pressure was about 100 microns, leaving the chamber in the linear range with respect to intensity versus ion current and with $\tau \gg 1$. Fifteen separate measurements with hydrogen as the source gas in the lamp gave an average value of 7.54 x 10^3 electrons/photon with a deviation of 3% for the quantum efficiency times gain with -3000

volts on the photocathode. The transmission of the window was measured both before and after the calibration and usually indicated about a 1.5% change after irradiation by Lyman-alpha. The quantum efficiency times gain, q' x g, at any other wavelength equals 7.54 \times 10 3 x response of photomultiplier relative to 1216 Å (See Figure 3.2).

3.5 Efficiency of the McPherson 218 Monochromator.

The efficiency of the monochromator at a given wavelength can be defined as the percentage of the incident radiation returned by the monochromator (grating and two mirrors) into a given order. It would have been very difficult to illuminate the grating in the same manner as in the excitation experiment. In the cross-section measurements of the Lyman-Birge-Hopfield system, the horizontal center line of the grating received most of the light. The effect of non-uniform lighting arises from the fact that LBH radiation is an extended source with an emission rate that varies as the distance from the electron beam. (See Chapter IV for the derivation of the relationship between integrated intensity at the slit as a function of minimum distance from the electron beam). The change in intensity from the center of the grating to the top or bottom of the grating was only about a factor of 2 with a slit height of 4 mm. The atomic nitrogen line radiation was caused by a line source that illuminated about 7 mm of the grating or about 20% of the grating.

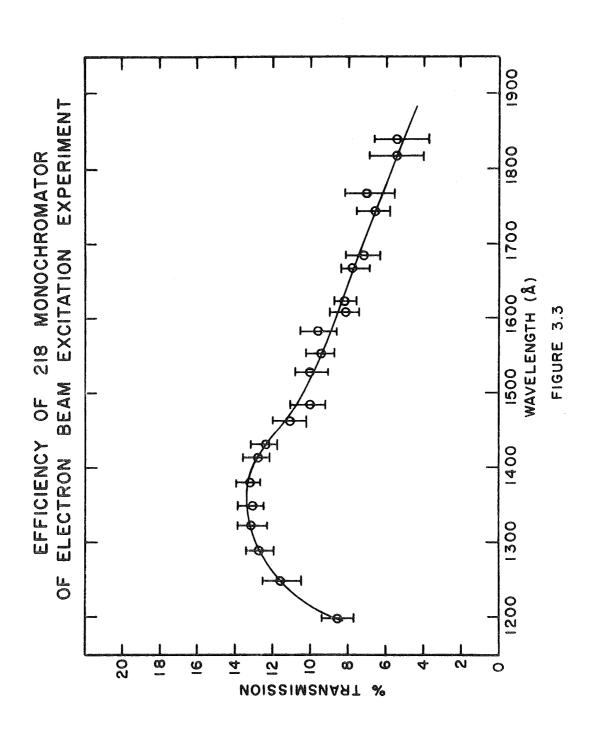

The efficiency of the monochromator was measured by putting the 218 in series with the McPherson 225 spectrometer. The 225 served as a monochromatic light source for the 218. The two spectrometers were physically separated by 4 inches. The exit slit of the 218 was used as the entrance slit and the entrance slit was used as an exit slit. This set-up was necessary to permit a physical coupling of the two monochromators. Since the grating equation was invariant to interchanging the entrance and exit angles with respect to the normal of the grating, the first order spectrum was imaged on the entrance slit. When the grating is illuminated in this direction, a fraction of the diffracted beam strikes the steep edge of the grooves, producing scattered light. Because of the large light output of the Hinteregger lamp, the signal to noise ratio was still very high. For example, the noise current on the photomultiplier measuring the exit beam increased from 0.2×10^{-12} amps in normal operation to 0.6×10^{-12} amps with the grating reversed. The monochromatic radiation exiting the 225 was made diffuse by a lithium fluoride diffusing plate, supplied by Harshaw Chemical Company of Cleveland, Ohio. The diffusing plate was placed 1 3/4 inches from the entrance slit of the McPherson 218. The diffusing plate had a 2 mm x 4 mm slit aperture stop in back of it with the long dimension horizontal. The entrance slit of the 218 was set to an opening of 400 microns with a slit

height of 2 mm. This geometrical configuration uniformly illuminated about 70% of the grating. The incoming monochromatic radiation was monitored by a 541 G-08-18 EMR side window photomultiplier suspended from a vacuum mechanical feed-through. The side window photomultiplier was placed 1 3/4 inches from the entrance slit and could be moved vertically in and out of the entrance beam. The exit beam was monitored by a 541 G-08-18 EMR end on photomultiplier. Another top was purchased for the 218 in order to mechanically mount and vacuum seal the side window photomultiplier. The side window photomultiplier was aligned vertically, horizontally, and angularly by electrical means before pump down by observing the zero order spectrum. Calibration points were obtained at 21 wavelengths between 1200 and 2000 Å. A ratio, $R_{\chi'}$ was determined for each of these wavelengths of the exit beam intensity to the entrance beam intensity.

The two photomultipliers were compared as to sensitivity, S , on the McPherson 225. The efficiency, ϵ , of the spectrometer at each wavelength was then calculated by

$$\epsilon_{\lambda} = R_{\lambda} S_{\lambda}$$
 (3.8)

The efficiency of the monochromator is displayed in Figure 3.3. The peak transmission of the spectrometer was 13.4% at 1383 $\mathring{\rm A}$. The result was surprising in that the grating was blazed at 1500 $\mathring{\rm A}$.

This effect was probably due to the reflectivity of the two mirrors having higher reflectivities at shorter wavelengths. The transmission of the monochromator was also measured without the diffusing plate and was 10% lower. In this case, only the center of the grating was illuminated. The change could be interpreted as either a variation in efficiency across the grating and mirror surfaces or as a polarization characteristic of the monochromator. The latter effect implies that the light from the first monochromator is polarized. The state of polarization would be different when the diffusing plate is inserted in front of the beam. The diffusing plate would tend to unpolarize the light beam. Thus, there was a 10% uncertainty introduced by the different geometrical configuration of the incident radiation of the experiment and the calibration.

CHAPTER IV

THEORY

4.1 Introduction

The theory of cross-section measurements can be divided into two parts. First, the theory of excitation of a particular energy level in an atom or molecule can be considered from the standpoint of the interaction of an electron with an atom or molecule. Depending on the energy of the impinging electron, there are probabilities or cross-sections for the type of reaction that can occur during the collision: for example, excitation, ionization, elastic scattering and dissociation for a molecule. In this thesis, the main theoretical and experimental interest lies in electron excitation and electron dissociative excitation. Secondly, after the collision the loss of the excitation energy by spontaneous emission of radiation by the atomic or molecular system must be looked at in detail to formulate a theory that balances the steady-state emission and excitation of each energy level being studied. For a permitted transition, the production and loss of excited atoms or molecules per unit volume may be considered equal since the radiation is emitted practically instantaneously (of the order of 10^{-8} seconds). However, for a forbidden transition, such as the Lyman-BirgeHopfield transition, the product of velocity and the lifetime of the vibrational levels are of such order that molecular flow must be included in the balance of production and loss per unit volume.

The basic physical processes and the geometrical problems involved for determining the apparent excitation cross-section of molecular nitrogen for the forbidden Lyman-Birge-Hopfield transition in an electron beam experiment are considered. The primary reaction is

$$N_2 (X^1 \Sigma_g^+) + e \stackrel{Q'}{\longrightarrow} N_2 (a^1 \Pi_g) + e ,$$
 (4.1)

followed by

$$N_2 (a^1 II_g) \rightarrow N_2 (X^1 \Sigma_g^+) + h \nu_{LBH},$$
 (4.2)

where $Q'_{\rm ov'}$ is the apparent excitation cross-section for excitation to the v' vibrational level of the $a^1\Pi_g$ state of molecular nitrogen. For the dissociative transitions considered in this thesis, the primary reactions are:

a)
$$V_{2}^{'}(^{4}P)$$

 $V_{2}^{'}(X^{1}\Sigma_{g}^{+}) + e \rightarrow N(^{4}P) + N + e , (4.3)$

b)
$$N_2(x^1\Sigma_g^+) + e \rightarrow N(^2P) + N + e$$
,

a)
$$N_2(X^1\Sigma_g^+) + e \rightarrow N(^4P) + N^+ + 2e$$
, (4.4)

b)
$$N_2(x^1\Sigma_g^+) + e \rightarrow N(^2P) + N^+ + 2e$$
,

$$N(^{4}P) \rightarrow N + h \nu_{1200\mathring{A}}$$
 (4.5)

$$N(^{2}P) \rightarrow N + h \nu_{1493\text{Å or }1743\text{Å}}$$
 (4.6)

where:

- Q'D1 (^4P) is the apparent dissociative excitation cross-section leading to a photon at λ = 1200 Å,
- $\rm Q_{\rm D_{\rm I}}^{'}$ ($^{\rm 2}\rm P)$ is the apparent dissociative excitation cross-section leading to photons at 1493 Å and 1743 Å,
- $Q_{D_2}^{'}$ (⁴P) is the apparent dissociative ionization excitation cross-section leading to a photon at $\lambda = 1200 \text{ Å}$.
- $Q_{D_2}^{'}$ (2 P) is the apparent dissociative ionization excitation cross-section leading to photons at λ = 1493 Å and 1743 Å.

Since it is impossible to distinguish 4.3 and 4.4 above the threshold for 4.4, the sum of the apparent cross-sections for

both processes are measured. Thus,

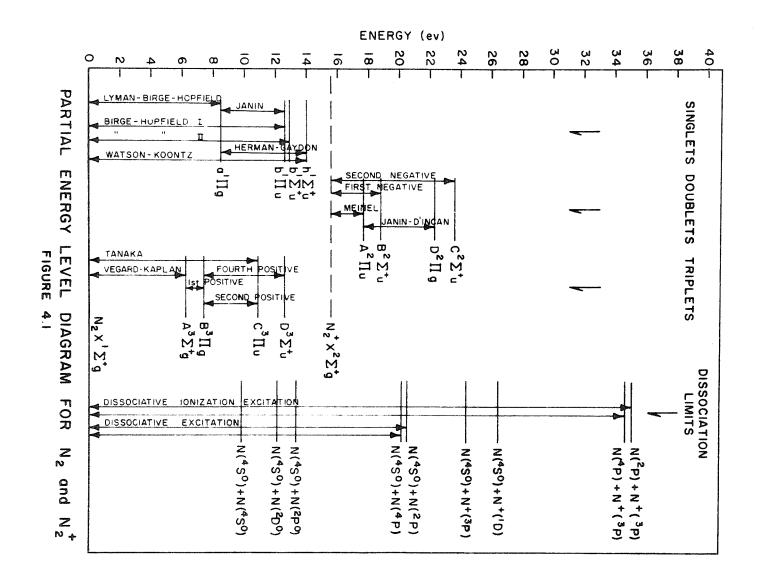

$$Q_{D}^{'}(^{4}P) = Q_{D_{1}}^{'}(^{4}P) + Q_{D_{2}}^{'}(^{4}P),$$

$$Q_{D}^{'}(^{2}P) = Q_{D_{1}}^{'}(^{2}P) + Q_{D_{2}}^{'}(^{2}P)$$
,

where it must be remembered that $Q_D^{'}$ (2P) is actually the sum of two partial cross-sections due to the branching of the 2P level leading to the 1493 Å multiplet and 1743 Å multiplet. In the thesis, both the terms emission cross-section and apparent cross-section are used. The term emission cross-section signifies a measurement of apparent cross-section (cross-section uncorrected for cascading) by optical means.

4.2 Energy Level Diagram of Molecular Nitrogen.

The energy level diagram of molecular nitrogen and once ionized molecular nitrogen is shown in Figure 4.1. The a $^{1}\Pi_{g}$ state lies 8.55 eV above the zero vibrational level of the ground $X^{1}\Sigma_{g}^{+}$ electronic state. The spacing of the LBH vibrational levels is ω_{e} = 1692 cm $^{-1}$, or about 0.2 eV (Herzberg, 1950). The a $^{1}\Pi_{g}$ \rightarrow $X^{1}\Sigma_{g}^{+}$ transition is forbidden as an electric dipole transition. It is permitted as a magnetic dipole transition. The two types of transitions are not distinguished experimentally unless quadrupole lines are present. The high resolution spectra of Wilkinson and Mulliken (1957) showed the presence of S and

O branches (quadrupole lines). The maximum quadrupole contribution to the transition is about 13% of the total. The bands are single headed and degraded to the red, and consist of P, Q, R, S and O branches.

In Table 4.1 are shown some important selection rules for electronic transitions in diatomic molecules. Since $a^1\Pi_g \to \chi^1\Sigma_g^+$ is a $g \to g$ transition, it is forbidden by electric dipole selection rules.

From a study of the energy levels and electron configurations of molecular nitrogen such ad Mulliken (1957) and a list of observed transitions in nitrogen (Wallace, 1962) it appears there are about ten possible cascading transitions to the $a^1\Pi_g$ state, some permitted and some forbidden. Furthermore, some are permitted and some forbidden to the $X^1\Sigma_g^+$ ground state, making an estimate of cascading very difficult. The most important cascading transitions, since they are observed in discharge lamps, are of the form $^1\Sigma_u^+ \rightarrow a^1\Pi_g \text{ and }^1\Pi_u \rightarrow a^1\Pi_g.$ Transitions of this form are permitted to the $a^1\Pi_g$ state and also to the $X^1\Sigma_g^+$ ground state by electric dipole selection rules if the transitions involve a one electron jump. Thus, there is the possibility of both slow and fast cascade to the $a^1\Pi_g$ state. These upper states lie between 12 and 14 eV. The spectra due to cascading lie between 2000 Å and 3000 Å. No attempt was made to observe the spectra in this region. It is

TABLE 4.1 (continued)

where:

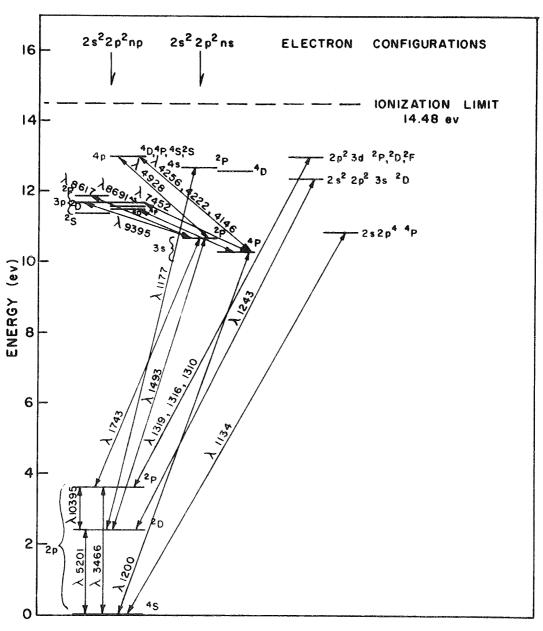

- J is the total angular momentum of the molecule, (disregarding nuclear spin),
- S is total electronic spin quantum number,
- Σ is total electronic spin quantum number projected along the internuclear axis,
- Λ is magnitude of orbital angular momentum of electrons projected on the internuclear axis,
- a, s, g, u, +, refer to symmetry properties of a molecule (See Herzberg, 1950).

determined in this experiment that the cascading contribution is less than 29%. (See Experimental Results, Chapter V). Furthermore, both this experimental measurement of emission crosssection and that of Holland (1969) find excellent agreement between measurement and prediction on the basis of Franck-Condon factors for direct electron excitation of the $a^{l}\Pi_{g}$ state as to the fraction of the total cross-section from each vibrational level. This relationship implies that cascading is a small effect, probably much less than 29%. There is also evidence that cascading is a small effect in auroral measurement of the LBH system (Miller, Fastie and Isler, 1968).

A transition that enabled one to "see" the beam was the first negative band system of N_2^+ ($B^2\Sigma_u^+ \to X^2\Sigma_g^+$). Its most prominent feature is the (0,0) band at 3914 Å. It made the beam appear blue.

The first dissociation limit of nitrogen is at 9.8 eV. The dissociation products consist of two ground state $^4\mathrm{S}^{\mathrm{O}}$ nitrogen atoms. The corresponding dissociative ionization limit of N_2^+ is at 24.3 eV and gives rise to dissociation products—atomic nitrogen in the $^4\mathrm{S}^{\mathrm{O}}$ electronic state and a once ionized nitrogen atom in the $^3\mathrm{P}$ electronic state. Dissociative excitation is observed in the experiment. The multiplets observed at 1200 Å, 1493 Å, and 1743 Å,

are from ${}^{4}P \rightarrow {}^{4}S^{O}$, ${}^{2}P \rightarrow {}^{2}P^{O}$ electronic transitions of atomic nitrogen, respectively, and are caused by dissociative excitation. The total transition probability of the multiplet at 1493 \mathring{A} , is $5.5 \times 10^8 \text{ sec}^{-1}$, and at 1743 Å is $2.0 \times 10^8 \text{ sec}^{-1}$ (see Table 4.2). The transition probabilities are taken from a compilation of atomic transition probabilities by Wiese, Smith and Glennon (1966). The branching ratios for multiplets for the transition from the $^2\mathrm{P}$ term would be 0.74 and 0.26, respectively. These lines originate from simultaneous dissociation and excitation of molecular nitrogen into one excited nitrogen atom (excited to one of the aforementioned electronic states) and a nitrogen atom or nitrogen ion. From experimental measurements at threshold, the ground state nitrogen atom or ion may be one of the products. Since there are other dissociation limits for N_2 and N_2^+ , it is also possible the nitrogen atom or ion may be in other than a ground state configuration. There is also the possibility of a cascade contribution to the ${}^{2}P$ and ${}^{4}P$ states since there are many permitted transitions to these levels. (See the energy level diagram of NI, Figure 4.2). The minimum energy needed to produce one of these lines is the sum of the minimum dissociation energy for creating two nitrogen atoms (one in the ground state configuration), plus the electronic excitation energy (10.33 eV for the 1200 \mathring{A} multiplet and 10.69 eV for the 1743 \mathring{A} and 1493 Å multiplet) above the ⁴S^O ground state of NI. The minimum

energies are 20.1 eV for the 1200 \mathring{A} multiplet and 20.5 eV for the 1493 \mathring{A} and 1743 \mathring{A} multiplets.

The minimum energies for dissociative ionization excitation is 34.6 eV for the $^4\mathrm{P}$ term and 35.0 eV for the $^2\mathrm{P}$ term. Thus, these atomic nitrogen lines are produced by excitation, either to a repulsive potential curve or to a stable potential curve with an equilibrium distance very different from the ground state potential curve of N₂, such that by Franck-Condon factor consideration, the excitation is to the continuum of nuclear levels. The dissociation products can have relative kinetic energy as well as internal electronic excitation energy.

4.3 Band Volume Emission Rates.

The factors determining the volume emission rate of a molecular band (v', v") will be briefly reviewed and applied to the LBH band system. The development of the theory of volume emission rates is analogous to the approach of Nicholls (1963), Chamberlain (1961), and McEwen (1965) for band intensities.

The Einstein A coefficient, the transition probability, can be expressed in a way similar to atomic transitions. Thus for electric dipole, magnetic dipole and electric quadrupole transitions, respectively, the following equations hold:

a)
$$A_{v'v''}^{E} = \frac{64\pi^{4}}{3h} \frac{S_{v'v''}^{E}}{g_{v'}^{3}} \sec^{-1}$$
, (4.7)

b)
$$A_{v'v''}^{M} = \frac{64\pi^4}{3h} \frac{s_{v'v''}^{M}}{g_{v'}\lambda^3_{v'v''}} \sec^{-1}$$
,

c)
$$A_{v'v''}^{Q} = \frac{32\pi^{6}}{5h} \frac{S_{v'v''}^{Q}}{g_{v'}\lambda_{v'v''}^{5}} \sec^{-1},$$

where:

S v'v" is the band strength, the superscript denoting electric dipole, magnetic dipole and electric quadrupole transitions, respectively,

 $g_{v'}$ is the statistical weight of the upper level,

 λ_{TIVE} is the wavelength of the emitted photon.

The band strength in the general case is defined as,

$$S_{V'V''} = | \int \Psi_{V'} R_{e}(r) \Psi_{V''} dr |^{2}$$
 (4.8)

where:

 $\Psi_{_{\mbox{$V'$}}}$ and $\Psi_{_{\mbox{$V''$}}}$ are the vibrational wave functions of the $_{\mbox{$V'$}}$ and $_{\mbox{$V''$}}$ are the vibrational wave functions of the

r is the internuclear separation,

R_e(r) is the electronic transition moment of the band system, defined as follows for the three types of transitions:

a)
$$R_e^E(r) = \int \Psi_{ev'}^* P_e \Psi_{ev''} d\tau , \qquad (4.9)$$

b)
$$R_{e}^{M}(r) = \int \Psi_{ev'}^{*} M \Psi_{ev''} d\tau ,$$

c)
$$R_e^Q(r) = \int \Psi_{ev'}^* R \Psi_{ev''} d\tau$$
,

where:

 $\Psi_{
m ev'}$ and $\Psi_{
m ev''}$ are the molecular electronic wave functions, dau is an element of configuration space,

 P_{e} , M and R are the electric dipole, magnetic dipole and electric quadrupole moments, respectively.

The electronic transition moment is most often a slowly varying function of internuclear separation. If it has the same functional dependence on r for all bands being analyzed, it may be expressed (Fraser, 1954) as R $_{\rm e}$ ($\bar{\rm r}_{{
m V'V''}}$) where $\bar{\rm r}_{{
m V'V''}}$, the r centroid, is the mean internuclear separation in the transition.

The r centroid,

$$\bar{\mathbf{r}}_{\mathbf{V'V''}} = \frac{\int \Psi_{\mathbf{V'}} \Psi_{\mathbf{V''}} \mathbf{r} d\mathbf{r}}{\int \Psi_{\mathbf{V'}} \Psi_{\mathbf{V''}} d\mathbf{r}} ,$$

is, thus, a characteristic internuclear separation associated with the band.

The band strength may be written as

$$S_{v'v''} = R_e^2 (\overline{r}_{v'v''}) q_{v'v''},$$

where

$$q_{V'V''} = \int \Psi_{V'} \Psi_{V''} dr |^2$$

the vibrational overlap integral is called the Franck-Condon factor of the band.

The volume emission rate, $\mathbf{I}_{\mathbf{V'V''}}$, of a molecular band, in units of photons $\text{sec}^{-1}~\text{cm}^{-3}~\text{is}$

$$I_{V'V''} = N_{V'} A_{V'V''}$$
, (4.10)

where $N_{\mathbf{V'}}$ is the number of excited molecules in the $\mathbf{v'}$ vibrational level per cubic centimeter.

Thus, the equation for volume emission rate may be written for each type of transition as follows:

a)
$$I_{V'V''}^{E} = C_{1} N_{V'} \nu^{3} (R_{e}^{E})^{2} q_{V'V''}$$
, (4.11)

b)
$$I_{v'v''}^{M} = C_2 N_{v'} \nu^3 (R_e^M)^2 q_{v'v''}$$
,

c)
$$I_{v'v''}^{Q} = C_3 N_{v'} \nu^5 R_e^{Q^2} q_{v'v''}$$

where the C's are constants, incorporating constants of Eqn. 4.7.

For the LBH band system, the volume emission rate may be written as

$$\begin{split} I_{v'v''} &= I_{v'v''}^{M} + I_{v'v''}^{Q} \\ &= K'N_{v'} \quad \nu^{3} \left[\left(R_{e}^{M} \right)^{2} + \alpha \nu^{2} \left(R_{e}^{Q} \right)^{2} \right] q_{v'v''} \quad , \end{split}$$

where K' and α are constants.

If it is assumed that the dependence of R_e^M and R_e^Q on $\overline{r}_{V'V''}$ are of the same form, the contribution of the quadrupole transition varies from 14% at 1300 Å to 6% at 2000 Å from the effect of the ν^2 term (McEwen, 1965).

Thus with this assumption and the fact the wavelength dependence is small, it can be written that

$$I_{v'v''} = K'N_{v'} v^3 R_e^2 q_{v'v''}$$
, (4.12)

where R_e^2 ($\bar{r}_{v'v''}$) now contains the two transition moment terms and is an effective transition moment.

The greatest influence over the intensity distribution is the Franck-Condon factor, $\mathbf{q}_{\mathbf{v'v''}}$, which varies over several orders of

magnitude across the band system. Franck-Condon factors for the LBH system are displayed in Table 4.3 (Benesch et al., 1966).

McEwen plotted $(I/q\nu^3)^{1/2}_{v'v''}$ versus $\bar{r}_{v'v''}$ for each of the upper bands v'=0 to v'=3, inclusive, to investigate the variation of the electronic transition moment as a function of internuclear separation. He found $(I/q\nu^3)^{1/2}_{v'v''}$ for the band system (which is proportional to R_e ($\bar{r}_{v'v''}$) to be a constant as a function of $\bar{r}_{v'v''}$ within 5%. The population factors $N_{v'}$ were divided out.

The band oscillator strength, f $$_{\rm V'V''}$$, which is a measure of the fraction of the optical electron associated with the transition is defined as

$$g_{V'V''} f_{V'V''} = \frac{8\pi^2 \text{ m c } S_{V'V''}}{3h e^2 \lambda_{V'V''}^2}$$
,

where:

m is the mass of the electron,

c is the speed of light,

e is the charge of the electron.

Thus,

$$f_{V'V''} = 1.5 \times 10^{-8} \lambda_{V'V''}^2 A_{V'V''}$$
, (4.13)

where λ is in microns, A is in \sec^{-1} .

Ching et al. (1967) measured the band oscillator strengths for the $a^{1}\Pi_{g}$ $\leftarrow X^{1}\Sigma_{g}^{+}$ transition in an absorption experiment for a v' progression, v" = 0. The absorption oscillator strength, the measured quantity, is related to the band oscillator strength by

$$g_{y''} f_{y''y'} = g_{y'} f_{y'y''}$$
 (4.14)

 $(f_{v''v'}$ is given in Table 4.4).

Thus, the lifetime of the LBH state can be calculated using Eqn. 4.13 and 4.14, and the equation

$$A_{V'V''} = \frac{2.026 \times 10^6 \text{ R}_e^2 \text{ q}_{V'V''}}{g_{V'} \lambda_{V'V''}^3}, \qquad (4.15)$$

where $g_{V'}=2$, due to λ doubling of the LBH state, and R_e^2 is determined from the absorption measurements of Ching et al. and McEwen's measurements showing R_e is a constant for the band system.

The result is a lifetime of approximately 37 microseconds for the LBH state where t, the lifetime, = $1/\Sigma_{V}$ "A $_{V'V'}$ ". This lifetime is to be contrasted with the 80 microsecond lifetime as measured by Holland in an electron beam experiment similar to this one. He measured the integrated intensity of the band system as a function of distance from an electron beam to obtain this value. One reason for this discrepancy would be a slow cascade

TABLE 4.4 Absorption Band Oscillator Strengths for the a ${}^{1}\Pi_{g}$ - ${}^{1}\Sigma_{g}^{+}$ Transition (Ching, Cook, and Becker, 1967)

contribution to the LBH lifetime. Holland's measurement of lifetime is the one used in the experimental calculations.

The reason for using Holland's data is that the cascade contribution to the LBH state appears to be small and Holland's measurement is a direct measurement of lifetime. If there is a slow cascade contribution to the LBH state, then Holland's measurements represent an upper limit to lifetime. To justify using the lifetime obtained from the absorption measurements, there would have to be evidence for a cascade contribution of 25% to 35%. From crosssection measurements near threshold, there is no evidence for a large cascade contribution.

4.4 Electron-Molecule Interactions.

The primary excitation reaction considered in this experiment is the interaction of low energy electrons (10 eV to 208 eV) with nitrogen molecules. The threshold for excitation of the a $^{1}\Pi$ state by electrons corresponds to 8.55 eV. The reaction is

$$N_2$$
 + e $\stackrel{Q_1}{\longrightarrow}$ N_2^* + e ,

where Q'_{OV} , (ϵ) is the apparent cross-section, or emission cross-section, for excitation of the v' vibrational level of the $a^1\Pi_g$ state from the zero vibrational level of the $X^1\Sigma_g^+$ state, uncorrected for cascading, by an electron of energy ϵ .

Thus, the interaction is an inelastic collision between electrons and nitrogen molecules in which some kinetic energy is lost by the electron in exciting internal motion in the molecule. The molecules dispose of their surplus energy by radiation and it is possible to determine the cross-section for excitation of the a $^{1}\Pi_{g}$ state by measurement of the absolute intensities of the emitted spectral bands.

If a molecule is excited by electron collision from vibrational levels (v") of the ground state to levels (v') of the upper state, the excitation probability, P_{XB} , per collision is proporational to the matrix element (Nicholls, 1962),

$$\mid \Psi_{V''} \Psi_{V'}^{\star} G_{XB,V''V'}^{\dagger} dr \mid^{2}$$
 .

 $G_{XB,v''v'}$ is the perturbation integral for the interaction between the electron and the molecule for a transition between the ground electronic state X and the excited electronic state B.

If $\boldsymbol{G}_{\boldsymbol{X}\boldsymbol{B}\,,\,\boldsymbol{V}''\,\boldsymbol{V}'}$ is a slowly varying function of internuclear separation, then

$$P_{XB} = \text{constant } G_{XB}^{2} \left(\overline{r}_{v'v''}\right) \left| \int \Psi_{v''} \Psi_{v'} \right| dr \left|^{2} \right|,$$

or

$$P_{XB} = \text{constant } G_{XB}^{2} (\bar{r}_{v'v''}) q_{v'v''}$$
.

That is,

$$Q_{ov'} = constant G_{XB,ov'}^2 q_{v'o}$$

The similarity between emission and excitation is pointed out in this approximation. In emission,

$$A_{v'v''} = \text{constant } R_e^2 (\overline{r}_{v'v''}) q_{v'v''} / \lambda_{v'v''}^3 .$$

Before showing how to calculate the cross-section for excitation experimentally, it is worthwhile to look at some of the other interactions between electrons and nitrogen molecules, such as elastic scattering, dissociation and ionization.

4.4.1 Elastic Scattering.

In addition to excitation, the primary electron may be elastically scattered. In an elastic collision, no energy interchange takes place between the internal motion of the molecule and the electron. The electron loses some energy in these encounters, but this is from the finite ratio of the mass, m, of the electron to that M of the molecule. As a result, a fraction of about 2 m/M of the initial kinetic energy of the electron is lost in an elastic collision. This fraction is less than 10^{-3} and may

be neglected. It is desirable to have very few of the primary electrons undergo elastic scattering, since the electron path through the chamber of elastic scattered electrons would be helical; thus, increasing the path length of electrons across the chamber. To keep this effect small, it is necessary to have the mean free path for elastic scattering much greater than the 6 inch length of the beam. Elastic scattering cross-sections are about 8.8 x 10^{-16} cm² (Massey and Burhop, 1952) at energies of 10 to 40 eV. The mean free path for elastic scattering, $\lambda_{\rm g}$, is

$$\lambda_{s} = \frac{1}{N_{o} \times Q_{s}} , \qquad (4.16)$$

where:

 $Q_s \cong 8.8 \times 10^{-16} \ \mathrm{cm^2}$ is the elastic scattering cross-section, N_o is the molecular nitrogen number density, and for the 0.2 microns pressure of this experiment, $N_o = 6.6 \times 10^{-12} \ \mathrm{cm^{-3}}$. Thus, $\lambda_s = 172 \ \mathrm{cm}$, which is much greater than the 15 cm path length of the electrons. It is expected that at higher pressures, elastic scattering of the primary electrons will be one cause leading to a nonlinear pressure dependence between intensity and pressure.

4.4.2 Dissociation.

The LBH transition represents an electronic transition from one potential curve that has an equilibrium separation or potential

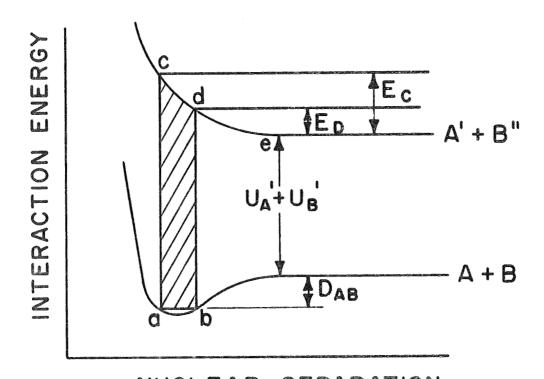

energy minimum to another potential energy curve with a potential energy minimum. Thus this is a transition that involves a stable molecule before and after the electron jump. In dissociation such as that exciting the atomic nitrogen lines, the final state of an electronic transition resulting from an electron impact lies within the continuum of nuclear motion. In this case, dissociation of the molecule accompanies all transitions from the lower to the upper electronic state. The dissociation products will have relative kinetic energy. In the transition, the final state is either a repulsive molecular state or a stable state with an equilibrium distance which is different from the equilibrium distance of the ground state potential energy curve such that by Franck-Condon considerations, dissociation always results. Figure 4.3 shows a hypothetical transition from a stable ground state to a repulsive molecular state. The minimum energy to produce the transition is (Massey and Burhop, 1952)

$$\epsilon_{\min} = U_A' + U_B'' + D_{AB} + T_{\min}$$

where:

D_{AB} is the dissociation energy of AB,

T_{min} is the minimum energy of relative motion of the resulting atoms after the transition, and lies between

NUCLEAR SEPARATION

DISSOCIATIVE ELECTRONIC TRANSITION

OF A MOLECULE FROM A STABLE STATE

TO A REPULSIVE STATE.

FIGURE 4.3

 $\epsilon_{\rm c}$ and $\epsilon_{\rm d}$ (see Figure 4.3),

This relation can be easily understood from the Franck-Condon factor which can be summarized; in an electronic transition, the nuclear separation and velocity of relative motion alter to a negligible extent--the transition takes place so quickly that due to the great ratio of nuclear to electronic mass, the nuclei have no time to move an appreciable distance. Thus, on the diagram, the transition is vertical, and takes place at a value of r such that the velocity of the nuclei is unchanged during the transition. Originally, the nuclear separation in the ground vibrational level will effectively lie between the limits a and b. Hence, finally, according to the Franck-Condon factor, it must also lie within these limits after the transition. For the case of a transition to a stable state whose potential energy minimum lies at a different equilibrium distance than the potential energy minimum of the ground state, a similar diagram can be drawn. In this instance, points c and d will be in the continuum of nuclear levels of the final state. Thus, the stable state (if any) of the final state lies outside the region determined by points c and d and are, thus, unreachable by the Franck-Condon principle. In this experiment the stable state is the ground vibrational state of $\mathbf{N}_2^{}.$ The unstable

state is one of the dissociative transitions leading to the formation of the 1200, 1493 or 1743 Å line.

There is no theoretical curve available of the shape of the unstable state to estimate T_{\min} . The actual shape of the curve is unimportant since it does not affect the cross-section measurement and since all that can be determined is an estimate of T_{\min} from threshold measurements. Thus, although the dissociation energy is defined as $U'_A + U''_B + D_{AB}$, this energy may bear no simple relation to the energy required to produce the dissociated molecule. Mulliken (Massey and Burhop, 1952) has, therefore, defined the vertical dissociation or ionization energy as a more useful quantity. From the experimental measurements around threshold T_{min} is about 1 eV for both dissociative transitions considered. These numbers were obtained by linearly extrapolating cross-section measurements to zero cross-section on a linear plot as a function of energy. One reason for the inability to determine \mathbf{T}_{\min} more accurately is that this treatment is only approximate since there is a small, but finite chance of dissociation of the molecule if it receives less than the vertical energy, that is, the transition from b to e (see Figure 4.3) is theoretically of small but finite probability.

4.4.3 Ionization.

For electron beam energies greater than $15.5 \, \mathrm{eV}$, it is possible to ionize N_2 into N_2^+ . These cross-sections rise steeply from zero at the threshold, peak at an electron energy several times the threshold and then decrease slowly at higher energy. For ionization of N_2 the peak is at about $100 \, \mathrm{eV}$. Thus, in an electron beam experiment, the maximum number of secondary electrons produced per cm³ would be at $100 \, \mathrm{eV}$. These secondaries would be expected to produce a non-linearity of intensity versus pressure if the number of secondaries became large enough. It is desirable to have the mean free path of ionization to be much greater than the 6 inch length of the electron beam. At $100 \, \mathrm{eV}$ the cross-section for ionization is $3 \times 10^{-16} \, \mathrm{cm}^{-2}$ (Tate and Smith, 1932). Thus

$$\lambda_{\rm I} = \frac{1}{N_{\rm O} Q_{\rm I}} = 505 \, \rm cm \ ,$$

where:

 λ_{T} is the mean free path for ionization,

 $\mathbf{Q}_{\mathbf{I}}$ — is the total ionization cross-section of \mathbf{N}_2 ,

N is the number density of molecular nitrogen at 0.2 microns pressure.

It is thus expected that at 0.2 microns pressure, excitation by secondary electrons is negligible although it will contribute to a nonlinearity in intensity versus pressure measurements at higher pressures. This expectation is borne out in the experimental measurements of intensity versus pressure (see Chapter V).

4.5 <u>Steady State Emission and Excitation--The Lyman-Birge-</u> Hopfield Transition.

The primary reactions affecting the population of the $a^1\Pi_g$ state when an electron beam is incident on a neutral nitrogen gas of low pressure are:

a)
$$N_2 + e \stackrel{Q_{OV'}(\epsilon)}{\longrightarrow} N_2^* + e$$
, (4.17)

b)
$$N_2 + e \stackrel{Q_{OV''}(\epsilon)}{\longrightarrow} N_2^{**} + e$$
,

$$N_2^* \xrightarrow{A} N_2 + h\nu$$

- d) Diffusion or molecular flow of excited LBH molecules,
- e) Cascading,

$$N_2^{**} \to N_2^* (a^1 \Pi_g) + h\nu$$
.

Some other processes that may affect the LBH state at higher pressures are:

a) Elastic scattering of electrons,

$$N_2 + e \xrightarrow{Q_S} N_2 + e$$
, (4.18)

b) Collisional deactivation,

$$N_2^* + N_2 \rightarrow N_2 + N_2 + \text{kinetic energy}$$

c) Excitation by secondaries,

$$N_2$$
 + e (secondaries) $\rightarrow N_2^*$ + e,

d) Ionization,

$$N_2 + e \xrightarrow{Q} N_2^+ + 2e$$
,

e) Dissociative ionization,

$$N_2 + e \xrightarrow{Q_D} N^+ + N^* + 2e$$
,

f) Dissociation,

$$N_2 + e \rightarrow N + N^* + e$$
,

where:

- $Q_{\rm OV'}$ is the cross-section for excitation to a v' a $^{\rm l}\Pi_{\rm g}$ vibrational level from the ground vibrational state of N_2 by an electron of energy ϵ ,
- Qov" is the cross-section for excitation to a vibrational level of an electronic state other than the a $^{1}\Pi_{g}$ state from the ground vibrational state of N $_{2}$ by an electron of energy ε ,

is the radiative transition probability of the $a^1\Pi_g$ state, N_2^* is a nitrogen molecule excited to the $a^1\Pi_g$ state, N_2^{**} is a nitrogen molecule excited to an electronic state other than the $a^1\Pi_g$ state.

Thus, there are many reactions going on simultaneously when an electron beam impinges on a neutral gas. The primary interest in any atmosphere calculation would be the number of photons coming out of an a $^1\Pi_g$ vibrational level per electron of energy, ϵ , impinging onto the gas. This number is proportional to the emission cross-section which is related to the absolute cross-section. The emission cross-section is defined from the equation

$$Q_{OV'}(\epsilon) = Q'_{OV'}(\epsilon) - \sum_{V'''} Q'_{OV'''}(\epsilon) \frac{A_{V''''V'}}{\sum_{V} A_{V'''V'}},$$

$$(4.19)$$

where:

 Q_{OV}^{\prime} (ϵ) is the emission cross-section,

 $Q'_{\rm OV'}$, (ϵ) is the emission cross-section of any v' ' ' state higher on the energy level diagram than the a $^1\Pi_{\rm g}$ states (v'), but connected to it by a possible transition,

 ${\bf A}_{{\bf V}'}$, , , , , is the transition probability from the higher state to the a $^{1}\Pi_{_{\bf G}}$ state,

 $\Sigma_{v}^{A}_{v'}$'s the total transition probability from the v' 'state to all lower states.

The reactions described are completely general. In this specific application, with pressures below 0.2 microns, only reactions 4.17 a, b, c, d and e are of significance in determining the steady state LBH emission. Mean free paths for nitrogen-nitrogen collisions are greater than 50 cm, and mean free paths for elastic scattering of electrons are greater than 100 cm. The mean free path for excitation or ionization is greater than 300 cm. Thus, the steady state emission is determined by the balancing of 4.17 a, b, c, d and e for the LBH transition.

The theoretical problem of determining the emission cross-section of nitrogen for the forbidden Lyman-Birge-Hopfield transition from absolute intensity measurements of radiation emitted by molecules excited to the a 1 II state by an electron beam can be divided into four separate problems:

- (1) Calculation of the volume emission rate from the excited a $^{1}\Pi_{g}$ molecules as a function of r, the distance from the electron beam.
- (2) Calculation of the integrated intensity at the entrance slit, (photons/sec cm² steradian).
- (3) Calculation of total light input to the slit (in photon/cm² sec) by integrating over the solid angle of the field of view.

(4) Determination of cross-section by measuring the integrated band intensities with a photomultiplier and strip chart recorder.

These four calculations represent the geometrical and physical factors encountered in this particular problem. The most important physical process, other than the excitation and emission processes, is the radial molecular flow of the excited molecules away from the beam region due to the long lifetime (80 microseconds) of the $a^1\Pi_g$ state. The effect of cascading has been combined with the direct excitation cross-section to the $a^1\Pi_g$ state and contributes to the apparent excitation cross-section. The state can be populated by cascading ($^1\Sigma_u^+$ and $^1\Pi_u^- \rightarrow a^1\Pi_g^-$). The first calculation solves the physical problem of electron excitation followed by spontaneous radiation. The basic reactions are:

a)
$$N_2 + e \rightarrow N_2^* + e$$
, (4.20)

and

b)
$$N_2^* \rightarrow N_2 + h\nu$$
.

It assumes that the emission per unit length, and the excitation per unit length, are equal. The final two integrals, or calculations, account for the finite field of view (9°40') of the spectrometer and make the geometrical calculation of the fraction of the spontaneous

radiation seen by the spectrometer.

In the pressure range below 0.2 microns, there are no deactivations and no secondary processes. The flux of radiation, $F_{v'}$, seen at the entrance slit of the spectrometer from any v" progression, is proportional to pressure, cross-section, and electron beam current.

Thus,

$$F_{V'} \propto Q'_{OV'} (\epsilon) P_{O}$$
 (4.21)

where:

 $F_{v'}$ is the flux of radiation from a v' vibrational level of the $a^{1}\Pi_{g}$ state, incident on the entrance slit of the monochromator in units of photons/cm² sec,

P is the molecular nitrogen pressure,

J is the electron beam current.

The first three calculations give the constant of proportionality.

4.5.1 The Volume Emission Rate from the Excited a II Molecules g
as a Function of the Distance from the Electron Beam.

For the calculation of the volume emission rate from the a $^{1}\Pi_{g}$ molecules as a function of distance from the electron beam, let,

 ${\rm N}_{_{\rm O}}$ be the number density of ${\rm N}_{2}$ molecules in the collision chamber,

 $Q_{ov'}'$ (\$\epsilon\$ be the apparent cross-section for excitation of a neutral N_2 molecule to any vibrational level, v', of the a $^1\Pi$ state by electrons of energy, \$\epsilon\$,

e be the charge of the electron,

T be the temperature of the N_2 molecules,

A be the transitional probability from an a ${}^{1}\Pi_{g}$ v' vibrational level to the ground state,

S be the cross-sectional area of the beam,

m be the mass of the nitrogen molecule,

K be the Boltzman constant.

The basic assumption is that the excitation per unit length of the beam equals the emission per unit length. Furthermore, the geometry is one of cylindrical symmetry.

The production of a $^{1}\Pi_{\rm g}$ molecules in the v' vibrational level by an electron beam is

Production =
$$\frac{N_o Q'_{oV'} J}{eS}$$
 = $\#/cm^3$ sec. (4.22)
Define P = $\frac{N_o Q'_{oV'} J}{e}$ = $\#/cm$ sec =

Let F (v_r) dv_r be the velocity distribution function of N_2 molecules in cylindrical coordinates. Then, P F (v_r) dv_r is the number of excited molecules produced in the velocity range, $\overline{v_r}$ to $\overline{v_r}$ + $\overline{dv_r}$.

It can be shown that,

$$F(v_r) dv_r = 2\pi \left(\frac{m}{2\pi KT}\right) exp \left[-\frac{m v_r^2}{2KT}\right] v_r dv_r . \qquad (4.24)$$

The r subscript from $v_{\rm r}$ and the prime superscript from $Q_{\rm OV}^{,}$ will be omitted for convenience.

The probability of an excited molecule having a lifetime longer than a time, t, is e^{-At} . And, the probability of reaching a distance, r, is exp (-Ar/v).

The probability of decaying in t to t + dt is $Ae^{-At}dt$, or in r to r + dr is $A \exp(-Ar/v) dr/v$. Let $N_{V'}$ (r) be the number density of excited molecules in level v', then the emission in photons/sec in any volume element, $2\pi r drdz$ is

$$2\pi r A N_{v'}(r) drdz =$$

$$\int_{v=0}^{v=\infty} Pdz F(v) dv A \exp\left(\frac{-Ar}{v}\right) \frac{dr}{v} . \quad (4.25)$$

Therefore,

a)
$$I_{v'}(r) = \frac{N_{o} Q_{ov'} J}{e} \frac{m}{2\pi KT}.$$

$$A\left[\frac{1}{r} \int_0^\infty \exp\left[-\frac{mv^2}{2KT}\right] \exp\left[-\frac{Ar}{V}\right] dv\right], \quad (4.26)$$

where:

b)
$$I_{v'}(r) = \frac{N_o Q_{ov'} J}{\pi e v_m^2} A.$$

$$\int_0^{\infty} \frac{1}{r} \exp\left[-\frac{v^2}{v_m^2}\right] \exp\left[-\frac{Ar}{v}\right] dv,$$

define

$$x = \frac{v}{v_m}$$
.

Then

$$v_m dx = dv$$
.

Making this substitution into equation 4.26b, the following equation is obtained

$$I_{v'}(r) = \frac{N_{o} Q_{ov'} J}{\pi e} \frac{A}{v_{m}}.$$

$$\int_{0}^{\infty} \frac{1}{r} e^{-x^{2}} \exp\left[-\frac{Ar}{v_{m}x}\right] dx . \qquad (4.27)$$

By using the perfect gas law, $P_{o} = N_{o}KT$, and a temperature of 294°K, it is determined that,

$$N_O (cm^{-3}) = 3.28 \times 10^{13} P_O (microns)$$
 (4.28)

and using a molecular weight of 28 for N_2 , it is found that,

$$v_m = 4.163 \times 10^4$$
 cm/sec,

then,

$$\frac{I_{v'}(r)}{P_{o} \text{ (microamps) } Q_{ov'} \text{ (cm}^2)} =$$

$$7.824 \times 10^{20} \times \frac{A}{r} \int_{-\infty}^{\infty} e^{-x^2} \exp \left[-\frac{Ar}{v_m |x|}\right] dx$$
. (4.29)

Equation 4.29 is in the Hermite form for a numerical integration by computer program. A plot of

$$M_{v'}(r) = \frac{I_{v'}}{P_O J Q_{OV'}} \text{ versus } r$$

is shown in Figure 4.4 for various values of A.

The fraction of the volume emission rate, $I_{V'}$, from any particular (v'v") transition is $\beta_{V'V''}I_{V'}$, where $\beta_{V'V''}$, the branching ratio for emission, is determined by the transition probabilities of the vibrational bands. Thus,

$$\beta_{V'V''} = \frac{A_{V'V''}}{\Sigma_{V''} A_{V'V''}}.$$
 (4.30)

It is seen that the intensity or volume emission rate is a glow of cylindrical symmetry about the beam, the intensity falling off a

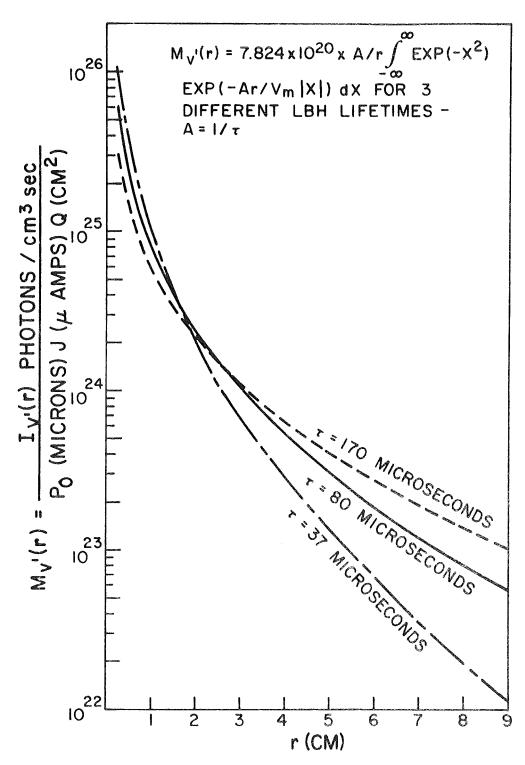

Figure THE SHAPE OF THE LBH GLOW REGION AS A 4.4 FUNCTION OF DISTANCE FROM THE ELECTRON BEAM FOR 3 LIFETIMES

little faster than 1/r due to the term, \exp (-Ar/ v_m |x|) in the integral. Since the assumption of an 80 microsecond lifetime for each vibrational level of the $a^1\Pi_g$ state is made, each vibrational level has a glow of the same relative shape. The absolute intensity or volume emission rate for each vibrational level of the $a^1\Pi_g$ state is proportional to Q_{OV} , all other factors being equal.

By multiplying both side of Eqn. 4.27 by $2\pi r$ dr and integrating from 0 to ∞ , it can be shown that the total emission per cm equals the total excitation per cm - N_O Q_{OV} , (ϵ) J/e.

4.5.2 Calculation of the Integrated Intensity at the Entrance Slit of the Monochromator.

Define "a" as the minimum distance to the beam from a line of sight, and p as the distance measured along the line of sight perpendicular to "a", then \aleph_{V} , the integrated intensity at the slit in photons/cm² sec steradian is

$$\alpha_{V'}$$
 (a) = $\frac{1}{4\pi} \int_{-\infty}^{\infty} I'_{V'}$ (p) dp. (4.31)

(See Figure 4.5)

The justification for this equation can be seen from the following considerations: The slit has an area A_s , and subtends an angle A_s/R^2 , as seen from the source. The number of photons

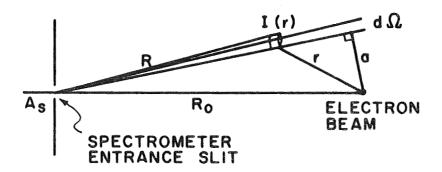

FIGURE 4.5 Geometry for line of sight calculation.

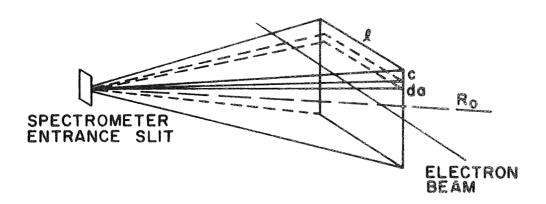

FIGURE 4.6 Geometry for the integration over the field.

reaching the entrance slit from an element of length dR = dp, and an area R^2 d Ω , perpendicular to the line of sight, is

$$\frac{A_s R^2}{4\pi R^2} I'_{v'}(p) dp d\Omega .$$

Thus, the total number of photons per ${\rm cm}^2$ per steradian per second at the slit from a v" progression is

$$\vartheta_{\mathbf{V}'} = \frac{1}{4\pi} \int_{-\infty}^{\infty} \mathbf{I}_{\mathbf{V}'}'(\mathbf{p}) d\mathbf{p}, \qquad (4.32)$$

where

$$r = (p^2 + a^2)^{1/2}$$

and

$$I'_{v'}(p) = I_{v'}(p^2 + a^2)^{1/2}$$
. (4.33)

Then,

$$\frac{\aleph_{v'}(a)}{P_{o} \text{ (microns)} \ Q_{ov'} \text{ (cm}^{2} \text{) J (microamps)}} = \frac{\aleph_{v'}(a)}{L_{v'}(a)} = \frac{1.2452 \times 10^{20} \ \text{A} \int_{-\infty}^{\infty} e^{-x^{2}}.$$

$$\frac{\Lambda}{\sqrt{2}} = \frac{1}{\sqrt{2} + \sqrt{2}} = \frac{1}{\sqrt{2}} = \frac{1}{\sqrt{2}}.$$

$$\exp \left\{-p\left[\frac{A}{v_{m}|x|} (1 + \frac{a^{2}}{p^{2}})^{1/2} - 1\right]\right\} dp$$
 (4.34)

Unity in the form, e^{-p} e^{+p} , is multiplied into the line of sight integral, Eqn. 4.34, to put it in the Laguerre form for a numerical integration. A plot of δ_{V} , versus a is shown in Figure 4.7.

4.5.3 The Total Light Input to the Slit from a v" Progression.

The total light input to the slit from a v" progression (in units of photon/cm 2 sec) is obtained by integrating $g_{V'}$ (a) over the solid angle of the field of view. The result is

$$F_{v'} = \int_{\Omega} a_{v'}(a) d\Omega(a) \qquad (4.35)$$

where:

 Ω (a) is the solid angle determined by the field of view of the spectrometer, d Ω (a) = ℓ da/R $_{O}^{2}$,

R is the distance from the slit to the beam,

is the width of field of view at the beam, its actual size depends on the width of grating projected onto the beam. (See Figure 4.6).

Thus,

$$\frac{F_{v'}}{P_{O} \text{ (microns) } J \text{ (microamps) } Q_{OV'} \text{ (cm }^2)} =$$

$$2 \frac{\ell}{R_{O}} \int_{0}^{C} L(a) da$$
 (4.36)

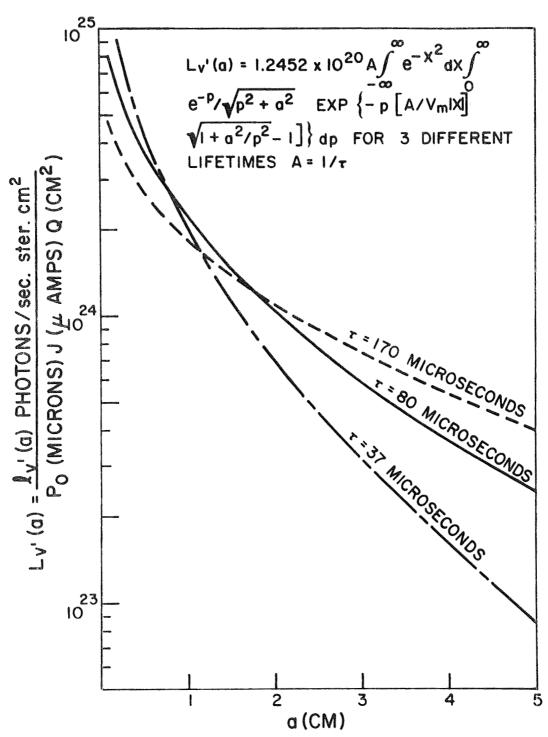

Figure THE INTEGRATED INTENSITY OF A v" PROGRESSION OF THE LBH SYSTEM AT THE ENTRANCE SLIT AS A FUNCTION OF MINIMUM DISTANCE FROM THE ELECTRON BEAM TO THE LINE OF SIGHT

where c is the height of the field of view at the beam.

Eqn. 4.36 is essentially a triple integral in the variables a, r, v, and can be determined by a suitable computer program once all the geometrical and physical constants have been determined. The result is a constant for a particular geometry. Thus

$$F_{v'} = k P_{o} \text{ (microns) J (microamps) } Q_{ov'} \text{ (cm}^{+2}\text{)} . (4.37)$$

k represents the triple integral of Eqn. 4.36, if the area of the slit is $\mathbf{A}_{\mathbf{s}}$, then

$$Z_{v'} = F A_s = k P_O J Q_{ov'} A_s$$
. (4.38)

is the experimentally measured quantity in photons/sec from a v" progression for a calibrated system.

In this experiment, $\ell=4.22$ cm. It is determined by projecting the width of the grating onto the beam. c is equal to 2.05 cm. It is determined by projecting the height of the grating onto the beam. The vignetting effect, caused by the finite height of the slit for the LBH bands, must be included in the calculation. Using these values for ℓ and c, and the fact R_0 is 24.924 cm, the value of k determined is

a)
$$k = 8.258 \times 10^{22}$$
, (4.39)

for t = 80 microseconds,

$$k = 9.800 \times 10^{22},$$

for t = 37 microseconds,

c)
$$k = 6.12 \times 10^{22}$$
,

for t = 170 microseconds.

The value of k used is determined from the 80 microsecond lifetime measured by Holland. If it turns out that one of the other values is more accurate, all cross-sections will have to be divided by the ratio of the proper k to 8.258×10^{22} .

Although this calculation is purely geometrical, it is important to note the effect of the variance of the three measured of calculated lifetimes. It is this lifetime which determined how much of the spontaneous radiation is seen by the spectrometer and photomultiplier tube. If t is very small, i.e., molecular flow is negligible, as in the case of the atomic nitrogen lines, then $k = 1.1607 \times 10^{23}$. Thus, the fraction of spontaneous radiation seen by the detection system is as follows for the various lifetimes:

Lifetime	Fraction of radiation detected
t = 37 microseconds	.84
t = 80 microseconds	.71
t = 170 microseconds	.53

4.5.4 <u>Determination of Cross-Section by Using a Photomultiplier</u> and Strip Chart Recorder.

By measuring the integrated band intensities with a calibrated photomultiplier, monochromator, and strip chart recorder, it is possible to determine $Z_{_{\mbox{V}'}}$ the light input per second from a v' vibrational level at the entrance slit of the monochromator. Consider the following quantities:

 $\mathbf{S}_{\mathtt{spec}}$ is the scan speed of the monochromator,

S_{rec} is the speed of the recorder chart paper,

w is the slit width in mm,

D is the dispersion of the instrument in Å/mm,

 ϵ_{λ} is the efficiency of the monochromator (grating

and two mirrors),

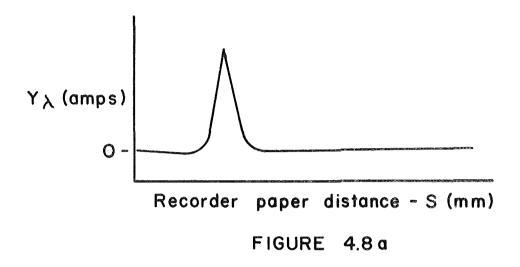

g is the gain of the PMT tube,

 q'_{λ} is the quantum efficiency of the PMT tube,

 au_{λ} is the transmission of the LiF window.

Figure 4.8a represents the output current versus time, or chart paper distance, for a particular band. Figure 4.8b represents the desired current caused by a linear transformation of Figure 4.8a to yield the total band intensity. If Y is the current output from the photomultiplier, then,

$$Z'_{\lambda} = \frac{Y}{wD}$$

LINEAR TRANSFORMATION OF OUTPUT FROM RECORDER VS CHART PAPER DISTANCE ->
BAND INTENSITY VS WAVELENGTH.

3 100

FIGURE 4.8 b

is the current output in amps per Angstrom. If s is the distance in mm along the chart paper, then,

$$d\lambda = \frac{S_{\text{spec}}}{S_{\text{rec}}} \times ds$$

and the output current of the photomultiplier, from any band -[v'v"] is

$$Z'_{V'V''} = \int Z'_{\lambda} d\lambda = \frac{S_{\text{spec}}}{S_{\text{rec}}} \times \frac{1}{\text{wD}} \int_{\text{band}} Y_{\lambda} ds$$
 (4.40)

 $\int\! \mathbf{Y}_{\lambda}\;\mathrm{d}\mathbf{s}\;\mathrm{is\;the\;area\;under}$ 4.8a in amp x mm.

To convert $\mathbf{Z'_{V'V''}},$ the current, or coulombs/sec, to photons/sec, it is noted that

$$\frac{Z'_{v'v''}}{e} = Z_{v'v''} \epsilon_{\lambda} q'_{\lambda} g \tau_{\lambda} .$$

Thus,

$$Z_{v'v''} = \frac{Z'_{v'v''}}{\epsilon_{\lambda} \operatorname{eq}'_{\lambda} \tau_{\lambda} g}, \qquad (4.41)$$

and

$$Z_{v'} = \Sigma_{v''} Z_{v'v''} = \Sigma_{v''} Z'_{v'v''} / \epsilon_{\lambda} eq'_{\lambda} \tau_{\lambda} g.$$
 (4.42)

Thus, from 4.38 and 4.42, where ϵ_{λ} and q_{λ}' vary slowly over a band, and λ corresponds to the wavelength of the center of a (v'v") band, it follows that,

$$Z_{v'} = \frac{S_{\text{spec}}}{S_{\text{rec}}} \times \frac{1}{\text{wD}} \times \frac{1}{\text{e}} \times \Sigma_{v''} \quad \left\{ \frac{v'v'' \text{ band}}{\epsilon_{\lambda}} \frac{\int Y_{\lambda} ds}{\tau_{\lambda}} \right\} (4.43)$$

and

$$\frac{\Sigma_{\text{spec}}}{S_{\text{rec}}} \times \frac{1}{\text{wD}} \times \frac{1}{\text{e}} \times$$

٧¹

$$\begin{array}{c} \text{k } P_{\text{O}} \text{ J } Q_{\text{OV'}} \text{ } A_{\text{S}} \text{ .} & (4.44) \\ \\ Q_{\text{OV'}} = \frac{1}{\text{k } P_{\text{O}} \text{ J A}} \text{ x } \frac{\text{S}_{\text{spec}}}{\text{S}_{\text{rec}}} \text{ x} \\ \\ \frac{1}{\text{wD}} \text{ x } \frac{1}{\text{e}} \text{ x } \Sigma_{\text{V''}} \left\{ \frac{\text{v'v'' band}}{\epsilon_{\lambda}} \frac{\int Y_{\lambda} \, \mathrm{ds}}{\lambda} \right\} \\ \end{array}$$

Thus, the total electronic Lyman-Birge-Hopfield cross-section is

$$Q_{LBH} = \Sigma_{V'} Q_{OV'} . \qquad (4.46)$$

In the experiment the various parameters had the following values:

a)
$$S_{\text{spec}} = 50 \text{ Å/mm}$$
 (4.47)

b)
$$S_{rec} = 1 \text{ mm/sec}$$

D =
$$13.9 \text{ Å/mm}$$

$$A_{s} = w \times 3.92 \text{ mm}$$

e)
$$k = 8.258 \times 10^{22}$$

where w, the slit width, was usually 0.200 mm, and 3.92 mm was the effective slit height. Thus, inserting these values into Eqn. 4.45, the following result is obtained,

$$Q_{OV'} = \frac{5.780 \times 10^{-18}}{P_O J w^2} \times$$

$$\frac{\sum_{v''} W_{v'v''} \times H_{v'v''} \times Scale_{v'v''}}{\epsilon_{\lambda} q^{\prime} q^{\prime} \chi^{\prime}}$$

$$\epsilon_{\lambda} q^{\prime} \chi^{\prime} \chi^{\prime}$$

where $\int Y_{\lambda} ds$ is approximated by a triangular band shape. The following experimental parameters are defined:

 $W_{v'v''}$ is the width of the band in mm,

 $H_{V^{'}V^{''}}$ is the height of the band in mm,

Scale $_{\rm V^{\prime}V^{\prime\prime}}$ refers to the scale on the picoammeter used to record the data. It is the sensitivity of the picoammeter-recorder combination. It has units of 0.1 picoamperes/mm.

The monochromator can be viewed as a black box with a certain transfer function. Its output is a convolution of the incident

radiation with the slit function. In the ideal case the slit function is triangular and the incident radiation a series of delta functions of various amplitudes. The resultant convolved output of the instrument is a series of triangles.

This is a very good approximation since at the $200\,\mu$ slit widths used, all band shapes were recorded as triangular, i.e., the instrumental width is much greater than the width of the band. It should be noted that the total cross-section for any vibrational level is the sum of partial cross-sections, due to the branching of the emission electron to various v" vibrational levels of the ground state. That is,

$$\beta_{V'V''} Q_{OV'} = Q_{V'V''} = \frac{5.780 \times 10^{-18}}{P_{O} J w^{2}} \times \frac{W_{V'V''} H_{V'V''} \times Scale_{V'V''}}{\epsilon_{\lambda} q_{\lambda} g_{\lambda} \lambda}, \qquad (4.49)$$

where we have defined $Q_{V'V''}$ as the emission cross-section for the [v'v''] band. This is the equation used for determining emission cross-sections for each [v'v''] vibrational band from the experimental data.

4.6 <u>Steady State Emission and Excitation--The Atomic Nitrogen</u> <u>Lines.</u>

Excitation of atomic nitrogen from the ground state of molecular nitrogen by dissociative excitation processes has been observed, and emission cross-sections determined.

The steady state equation relating population gain and loss of the j-th state of an atomic-molecular system in an electron beam dissociation process is

$$Q_{D}(j) = \frac{J N_{O}}{eS} + \sum_{i} N_{i} A_{ij} + transfer gain = N_{j} A_{j} + transfer loss,$$
 (4.50)

where:

 $Q_{\mathrm{D}}^{}$ (j) is the absolute cross-section for dissociative excitation (either ionization or pure dissociation) by electron impact from the ground state of molecular nitrogen to the j-th state of atomic nitrogen,

 $N_{\mbox{\scriptsize j}}$ is the number density of atomic nitrogen atoms in the j-th state,

 ${\rm N}_{\,i}$ is the number density of atomic nitrogen atoms in the i-th state,

 ${\tt A}_{ij}$ is the probability of transition from the i-th state to the j-th state,

 $\mathbf{A}_{\mathbf{j}}$ is the probability of transition from the j-th state to all lower states.

The transfer of excitation is negligible for pressures of 1 micron or less. The current strength in the beam is so small that

collisions between excited atoms and beam electrons may be neglected. Thus, it is found,

$$\frac{Q_D(j) J N_O}{e S} + \Sigma_i N_i A_{ij} = N_j A_j . \qquad (4.51)$$

It follows that if absolute intensity measurements are made of radiation, both to and from the j-th state, then the absolute cross-section $Q_{\rm D}$ (j) can be derived. What is usually measured in optical experiments of this kind is the absolute intensity variation with energy of radiation from the j-th state.

An apparent cross-section $Q_{\mathrm{D}}^{'}$ (j) is defined from the equation

$$Q'_{D}(j) = \frac{N_{O}}{S} = N_{j} A_{j}$$
 (4.52)

It is seen that the emission cross-section is related to the absolute cross-section by Eqn. 4.53 since the right hand sides of 4.51 and 4.52 are equal.

$$Q'_{D}(j) = \frac{J}{eS} N_{o} = \frac{Q_{D}(j) J}{eS} N_{o} + \sum_{i} N_{i} A_{ij}$$
 (4.53)

or

$$Q_{D}(j) = Q'_{D}(j) - \sum_{i} N_{i} A_{ij} \times \frac{eS}{J N_{O}}, \qquad (4.54)$$

but

$$Q'_{D}(i) = \frac{N_{i} A_{ij} A_{i}}{A_{ij}} \times \frac{eS}{J N_{O}}.$$
 (4.55)

Making this substitution into Eqn. 4.54, it follows that

$$Q_{D}(j) = Q'_{D}(j) - \sum_{i} Q'_{D}(i) \frac{A_{ij}}{A_{i}}$$
 (4.56)

This is the relation between emission of apparent crosssection and absolute excitation cross-section. The two crosssections are equal if cascading is negligible.

If experimentally, all that is observed is a particular transition from the j-th state to the k-th state, then

$$Q'_{D}(j) = \frac{N_{O}}{S} = N_{j} A_{j} = N_{j} A_{jk} \frac{A_{j}}{A_{jk}}$$
 (4.57)

or

$$\beta_{jk} Q_D'(j) = \frac{N_O}{S} = N_j A_{jk}$$
, (4.58)

where β_{jk} is the emission branching ratio from the j-th state to the k-th state.

We will drop the prime superscript and assume all crosssections are apparent or emission cross-sections. In particular, we are interested in the following dissociative reactions:

$$Q_{D_1}(^4P)$$
a) $N_2(X^1\Sigma_g^+) + e \rightarrow N(^4P) + N + e$, (4.59)

b)
$$N(^{4}P) \rightarrow N(^{4}S^{\circ}) + h\nu_{1200}$$
,

c)
$$N_2(x^1\Sigma_g^+) + e \rightarrow N(^4P) + N^+ + 2e$$
,

d)
$$N(^{4}P) \rightarrow N(^{4}S^{\circ}) + h\nu_{1200}$$
,

e)
$$N_2(X^1\Sigma_g^+) + e \rightarrow N(^2P) + N + e$$
,

f)
$$N(^{2}P) \rightarrow N(^{2}D^{\circ}) + h\nu_{1493}$$
,

g)
$$N(^{2}P) \rightarrow N(^{2}P^{\circ}) + h\nu_{1743}$$
,

i)
$$N(^{2}P) \rightarrow N(^{2}D^{\circ}) + h\nu_{1493}$$
,

j)
$$N(^{2}P) \rightarrow N(^{2}P^{\circ}) + h\nu_{1743}$$

where:

- Q_{D_i} (j) is a dissociative excitation reaction if i=1 where $j={}^4P, {}^2P,$
- Q_{D_i} (j) is a dissociative ionization excitation reaction if i = 2 where $j = {}^4P$, 2P .

 ${\rm Q_{D_i}}\,(^2{\rm P})$ can be further broken up into partial cross-sections, since a branching is involved:

$$Q_{D_i}^{(2P)} = Q_{D_i}^{(1493 \text{ Å})} + Q_{D_i}^{(1743 \text{ Å})}.$$
 (4.60)

It is not possible to distinguish the radiation from each type of dissociation above the threshold for dissociative ionization. Therefore, what is determined is the sum of cross-sections of the two types of dissociative transitions. That is,

$$Q_D = Q_{D_1}(j) + Q_{D_2}(j)$$
 (4.61)

This is the important quantity in any atmospheric calculation. There is the possibility of a cascade contribution to these crosssections, since there are many permitted transitions to the 2 P and 4 P levels. See the energy level diagram of NI (Figure 4.2).

4.7 Photometry for the Atomic Nitrogen Lines.

The geometrical calculation of the radiation detected is very similar to the determination of the Lyman-Birge-Hopfield

radiation detected, except, there are no molecular flow effects. From Eqn. 4.52,

$$I_{j} = N_{j} A_{j} = Q_{O}^{'}(j) \frac{J N_{O}}{eS}$$
 (4.62)

is the volume emission rate from the j-th state to all lower states. The emission per unit length of the beam is

$$\frac{Q_{D}(j) J N_{O}}{e}$$
.

The total emission from a small increment of length of the beam, $\mbox{d}\ell$, is

$$\frac{Q_{D}(j) J N_{o} d\ell}{e}.$$

The fraction of the radiation detected is equal to the solid angle subtended by the entrance slit, divided by 4π . This quantity is

$$\frac{Q_{\mathrm{D}}(j) \ J \ N_{\mathrm{O}} \ A_{\mathrm{S}} \ d\ell}{\mathrm{e} \ 4\pi \ R_{\mathrm{O}}^{2}} \ .$$

Thus the total radiation, in units of photons/sec, at the entrance of the spectrometer from the length, ℓ , of the beam in the field of view is

$$Z(j) = \frac{Q_D(j) J N_o A_s \ell}{e 4\pi R_o^2}$$
 (4.63)

or

$$Z(j) = K_D Q_D(j) P_O J A_S$$
, (4.64)

where \mathbf{K}_{D} is a constant of proportionality containing the geometrical factors.

Using the perfect gas law to determine \mathbf{N}_{O} in terms of \mathbf{P}_{O} , in microns, and where:

J is in microamps,

 ℓ is 4.22 cm,

R_O is 24.924 cm,

 A_{S} is 4 mm x w,

the following value of $K_{\overline{D}}$ is obtained,

$$K_D = 1.1607 \times 10^{23}$$
 (4.65)

Thus,

$$Q_{D}(j) = \frac{Z(j)}{K_{D}JP_{O}A_{s}}.$$
 (4.66)

Incorporating the monochromator and photomultiplier calibration factors into this equation in a similar way as in the LBH calculation, the following result is obtained for the total emission cross-section of the j-th electronic term of an atom in this experiment

$$Q_{O}'(j) = \frac{4.2269 \times 10^{-18}}{P_{O} J w^{2}}.$$

$$\sum_{\substack{k \\ \text{all final} \\ \text{states}}} \frac{W_{jk} H_{jk} Scale_{jk}}{\epsilon_{\lambda} q_{\lambda}' g \tau_{\lambda}}, \quad (4.67)$$

where:

 W_{ik} is the width of the line in mm from a $j \rightarrow k$ transition,

 H_{ik} is the height of the line in mm,

Scale $_{jk}$ is the sensitivity of the recorder-picoammeter combination in units of 0.1 picoamperes/mm,

w is the slit width in mm.

In particular, for the 1200 Å, 1493 Å and 1743 Å multiplets of atomic nitrogen, respectively, the individual emission cross-sections are:

a)
$$Q_D(1200) = Q_D(^4P) =$$

$$\frac{4.2269 \times 10^{-18}}{P_0 \text{ J w}^2} \frac{W_{1200} \text{ H}_{1200} \text{ Scale}_{1200}}{\epsilon_{1200} \text{ g} \tau_{1200}}, \quad (4.68)$$

b)
$$Q_{D}$$
 (1493) =

$$\frac{\text{4.2269} \times 10^{-18}}{\text{P}_{\text{O}} \text{ J w}^2} \qquad \frac{\text{W}_{1493} \quad \text{H}_{1493} \quad \text{Scale}_{1493}}{\epsilon_{1493} \quad \text{q}_{1493} \quad \text{g} \quad \tau_{1493}},$$

c)
$$Q_{D}(1743) =$$

$$\frac{4.2269 \times 10^{-18}}{P_{O} \text{ J w}^{2}} \frac{W_{1743} \text{ H}_{1743} \text{ Scale}_{1743}}{\epsilon_{1743} \text{ f}_{1743} \text{ g}_{1743}}.$$

$$Q_{D}(^{2}P) = Q_{D}(1493) + Q_{D}(1743). \qquad (4.69)$$

Equations 4.68 and 4.69 were the equations used to determine the dissociative excitation cross-sections of molecular nitrogen from the experimental data.

CHAPTER V

EXPERIMENTAL RESULTS

5.1 Introduction

The experimental results can be divided into two parts.

First, there were the linearity tests on the LBH band system and nitrogen lines. These were preliminary measurements to determine the range of electron beam currents and molecular nitrogen pressures in which the measured flux of radiation was linear in these two parameters. The basic equation for experimentally determining emission cross-sections is

$$F_{y'} = k P_{O} Q_{OY'}(\epsilon) J.$$
 (Eqn. 4.37)

This equation assumes the measured flux of radiation $F_{V'}$ is linearly proportional to the molecular nitrogen pressure in the chamber and the electron beam current. By varying P_{O} and J over a range of pressures and electron beam currents, respectively, it can be determined over what range $F_{V'}$ is linear in these parameters. For low enough pressures and electron beam currents, this equation is valid in determining cross-sections. For high pressures and/or electron beam currents, secondary processes become important.

Using the results of the linearity measurements, the electron beam chamber was maintained in the linear pressure and electron beam current regime for the cross-section measurement and the entire spectrum recorded between 1200 Å and 2000 Å. The emission cross-section for each LBH band and each nitrogen line was then determined using Eqn. 4.49 or Eqn. 4.68 of Chapter IV. The emission cross-sections of the LBH band system were summed to obtain a total cross-section for the entire electronic transition and total cross-sections for each vibrational level.

5.2 Pressure Dependence.

The pressure dependence of the flux of radiation from various bands of the LBH system was investigated for energies between 25 eV and 100 eV and for pressures from .03 microns to 1 micron. The results indicated that secondary processes became important at pressures greater than 0.2 microns, since non-linearity of flux versus pressure began at this pressure. The linearity tests were performed by focusing a particular band on the exit slit of the monochromator at a particular energy and changing the pressure in small increments, noting the current in the pico-ammeter, the pressure and the electron beam current. The three bands tested were the (1,1), (2,0) and (3,0). The results are displayed in Figures 5.1, 5.2 and 5.3. Consider for a moment

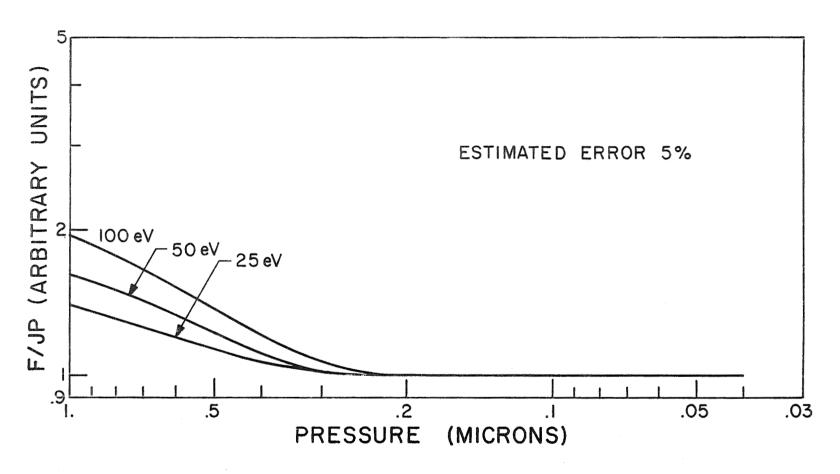

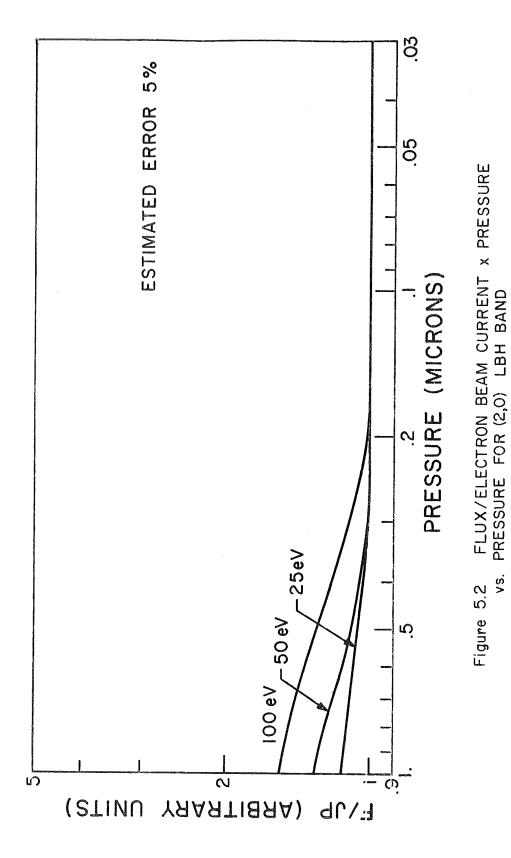

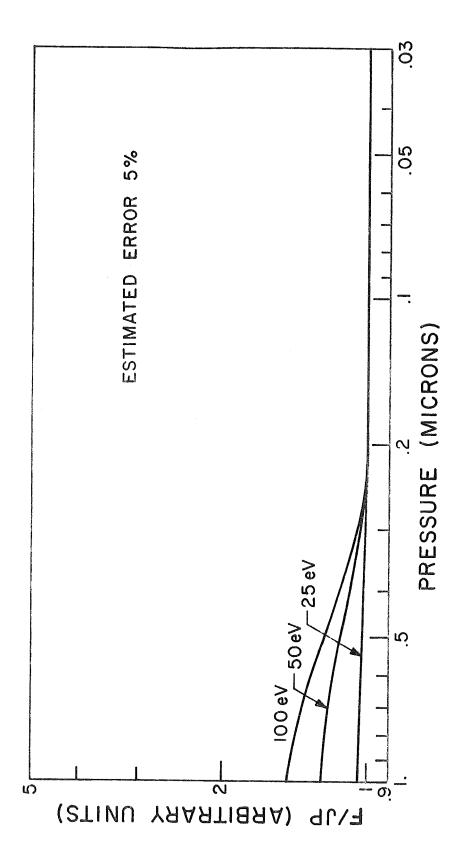

Figure 5.1 FLUX/ELECTRON BEAM CURRENT x PRESSURE vs. PRESSURE FOR (I,I) LBH BAND

FLUX/ELECTRON BEAM CURRENT x PRESSURE PRESSURE FOR (3,0) LBH BAND Figure 5.3

one band, say the (1,1) band in Figure 5.1. In this figure is plotted the flux of radiation in arbitrary units, divided by pressure and beam current versus pressure at three different energies, 25 eV, 50 eV and 100 eV. It can be seen that the ratio of flux divided by pressure was a constant for all these energies up to pressures of 0.18 microns. The non-linearity was greatest at 100 eV, and least at 25 eV for pressures greater than 0.18 microns. Similar results held true for the (3,0) and (2,0) bands. In other words, for pressures greater than 0.18 microns, the measured flux varied as a power of the pressure greater than one. This power depends on the energy and probably to a certain extent, on the currents used. For pressures between .8 microns and 1 micron, and for energies of 75 eV and 100 eV, there appeared to be a slight decrease in the slope of F/J P versus P, indicating that deactivation or vibrational energy exchange was beginning, due to the increased number of molecule-molecule collisions. The non-linearity is most strongly influenced by secondary electrons which can contribute to the excitation. The non-linearity is also determined by elastic collisions which can increase the effective path length of the primary electrons across the chamber. Since the peak cross-section of ${\rm N}_2$ for ionization by electron bombardment is at 100 eV, it would be expected that the non-linearity would be greatest at this energy. At 25 eV, the secondary electrons still have enough energy to excite the LBH band system. In these measurements, the electron beam

current is divided out. It is of the order of 150 microamps at energies greater than 50 eV, and 50 microamps at 25 eV. Since the number of secondaries produced is proportional to the electron beam current, a larger electron beam current would produce a greater non-linearity. The non-linearity also depends on the length of the electron beam, since a longer beam increases the number of collisions.

One more phenomena is of interest. A plot of the (1,1), (2,0) and (3,0) bands on the same relative scale at 100 eV (see Figure 5.4) indicated that the higher the v' vibrational level the smaller the pressure dependence. Thus, by collisions, there is a transfer of vibrational energy from higher vibrational levels to lower vibrational levels. Vibrational relaxation becomes more important as the pressure increases. Thus, vibrational levels are tending to a Boltzmann distribution, due to collisions.

The atomic nitrogen lines, on the other hand, have such a short lifetime that they will radiate before being perturbed by collisions. This idea was borne out in the F/J P versus P measurements. The nitrogen lines were linear with pressure from 50 eV to 100 eV over all pressures measured, .03 microns to 1 micron. However, the measurement at 25 eV indicated a non-linear effect above 0.2 microns for both the 1200 Å multiplet and 1493 Å multiplet. The cause of this effect would not be from secondary electrons, since

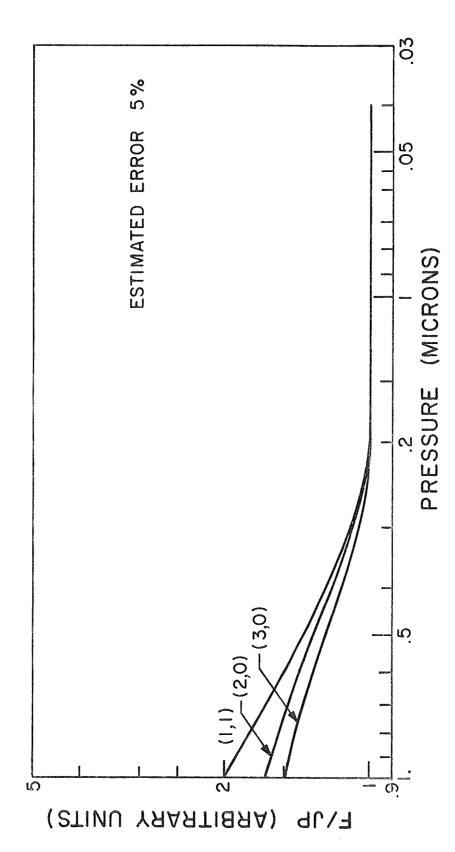

Figure 5.4 FLUX/ELECTRON BEAM CURRENT x PRESSURE vs. PRESSURE AT 100 eV

secondary electrons do not have enough energy to produce excitation. The cause in this case may be elastic scattering of primary electrons.

The results of the pressure measurements for the 1200 \mathring{A} multiplet and 1493 \mathring{A} multiplet are displayed in Figures 5.5 and 5.6 respectively.

5.3 <u>Electron Beam Current Dependence</u>.

In an analogous manner to the pressure dependence determinations, measurements were made of the ratio of the flux of radiation to electron beam current versus electron beam current for the (3,0), (2,0) and (1,1) LBH bands at 0.18 microns pressure, and for the nitrogen lines at 0.15 microns pressure, with several energies as parameters. These pressures were chosen to insure adequate intensity readings over the range of electron beam currents employed. The results indicated that the LBH bands were linear in beam current versus flux for electron energies from 15 eV to 100 eV. The range of currents measured was from 20 microamps to 300 microamps. The results for the (1,1) band are shown in Figure 5.7. The nitrogen lines were linear with current for energies of 50 eV and greater, and for currents less than 220 microamps. The 1493 Å line revealed a slight non-linearity for current greater than 220 microamps, and the 1200 \mathring{A} line did not. At 25 eV, both the 1200 \mathring{A}

line and 1493 Å line were non-linear for currents greater than 100 microamps. The results of the current linearity test for the nitrogen lines at energies of 100 eV and 25 eV are displayed in Figures 5.8 and 5.9, respectively. It should be remembered that the (3,3) LBH band overlaps the 1493 Å atomic nitrogen line. Similar linearity tests were performed on the 1743 Å transition of atomic nitrogen. The same conclusions held for this multiplet as for the 1493 Å multiplet.

5.4 Spectral Observations.

Spectral scans were made of the electron beam excitation spectrum of molecular nitrogen from 1200 Å to 1962 Å. During the spectral scans, at a particular electron beam energy, the electron beam current and molecular nitrogen pressure were monitored and recorded. The electron beam current remained constant to within 1 microamp. Currents used varied from 50 microamps at low energies to 200 microamps at high energies. Typical pressures were in the range, 0.12 microns to 0.18 microns. This range of pressure was chosen in order to obtain adequate intensity determinations for the LBH bands. The pressure remained constant to within 3% over any spectral scan. Any change in either current or pressure was recorded. A typical low pressure scan at 75 eV is shown in Figure 5.10. Three or four complete spectra were obtained at each

energy. A total of 25 energies from 100 eV to 208 eV was investigated for the LBH bands, and approximately the same number of energies were investigated for the nitrogen lines from 20 eV to 208 eV. The important quantity was the area under each band. This quantity, with the instrumental factors and calibration factors included was the number of photons/second entering the entrance slit of the monochromator. By dividing this number by the electron beam current, the area of the slit, the nitrogen pressure and the geometrical factor, k, the emission cross-sections were determined (Refer to theory, Chapter IV). Slits were normally 200 microns wide by 4mm high. The cross-section of the field of view at the beam was rectangular, 4, 10 cm, vertically by 4.22 cm horizontally.

The LBH bands observed in the experiment are listed by wavelength in Table 5.1. Listed with the bands is the quantity $f_{V'V''}$ which is the fraction of the total electronic cross-section contributed by each band, or partial cross-section, as calculated by using Franck-Condon factors for direct electron of the $a^1\Pi_g$ state (Holland, 1969). The quantity $f_{V'V''}$ is

$$f_{V'V''}' = \frac{Q_{V'V''}}{\Sigma_{V'}Q_{OV'}} = \frac{\beta_{V'V''}Q_{OV'}}{\Sigma_{V'}Q_{OV'}}$$

$$= \frac{q_{V'V''}\lambda_{V'V''}^{-3}}{(\Sigma_{V'}q_{V'V''}\lambda_{V'V''}^{-3})} \times \frac{q_{V'O}}{\Sigma_{V'}q_{V'O}}$$

TABLE 5.1 (continued)

Observed Emission Features, Between 1200 Å and 1962 Å, of Molecular Nitrogen by Electron Bombardment

- * These bands were not observed since they were beyond the wavelength cut-off of the instrument, but their partial cross-sections were calculated, using Eqn. 5.1, and their strength relative to the (3,0) band.
- These bands were overlapping LBH bands and the individual partial cross-sections were determined, using Eqn. 5.1 and 5.2.
- These bands overlapped with atomic nitrogen lines. Their cross-sections were measured from 10 eV to 18 eV and extrapolated to higher energy, using a normalized LBH cross-section curve.
- These two bands overlapped at energies greater than about 50 eV with the intense N_2^{++} (d' $\Sigma_g^+ \rightarrow$ d' Σ_g^+) transition of Carroll and Hurley (Holland, 1969).

This approximation is valid since McEwen (1965) has shown the electronic transition moment is a constant over the band system to within 5%. Also, in inelastic scattering experiments, Lassettre et al. (1968) found the relative probabilities of directly exciting the a $^{l}\Pi_{g}$ vibrational levels were proportional to the (v',o) Franck-Condon factors. Holland (1969) found excellent agreement by comparing his observations to this formulation. This agreement suggests that most of the LBH emission is from direct electron excitation. The Franck-Condon factors used in determining $f_{V^{l}V^{l}}^{'}$ were those of Benesch et al. (1966). Only $v^{l}=0$ to $v^{l}=6$ were included, since only two bands for $v^{l}>6$ were observed and these were weak, owing to the importance of predissociation for $v^{l}>6$.

The resolution of the monochromator was about 3 Å. Thus, if the bands were less than 3 Å apart, they could not be resolved. The numbers $f'_{V'V''}$ were used to separate about 20 overlapping bands. The contribution of each particular overlapping band to the crosssection was calculated from Eqn. 5.1. Consider two overlapped bands. The contribution to the emission cross-section of this spectral feature by the first band is

a)
$$\frac{f'_{v'_1} v''_2}{f'_{v'_1} v''_1 + f'_{v'_3} v''_4}$$
 (5.2)

and for the second is

b)
$$\frac{f'_{v'_1v''_1}}{f'_{v'_1v''_2}} + f'_{v'_1v''_1}$$

where:

 $f_{1}^{\prime}v_{2}^{\prime\prime}$ refers to the contribution to the total cross-section by the first band,

 $\mathbf{f}_{\mathbf{V'V''}}^{'}$ refers to the contribution to the total cross-section by the second band.

The numbers $f_{V'V''}$ were also used to calculate the partial crosssections of bands between 1962 Å and 2300 Å if their contribution to the total cross-section was greater than 0.2%. The intense (3,0) band, at 1353 Å, was used as a reference for these calculations.

It is seen from Table 5.1 that about 65 bands are observed, and the effects of about 10 more to the cross-section, are estimated. These bands represent about 96% of the electronic transition. The remaining 4% is distributed over about 30 weak bands. Three bands could only be observed up to the onset of dissociative excitation of molecular nitrogen. These bands were the (6,1), (4,2) and (3,3). The threshold for dissociative excitation is about 20 eV. Therefore, these bands were observed from 10 eV to 18 eV. This procedure gave enough points to extrapolate the cross-section to higher energy,

once the relative shape of the LBH cross-section curve was determined. Finally, the 1584 Å and 1591 Å bands were overlapped by an N_2^{++} transition for energies greater than about 50 eV. The cross-sections of these bands were also extrapolated to higher energy after the relative shape of the LBH cross-section curve was determined.

Table 5.2 gives a list of the observed atomic nitrogen multiplets. The only multiplets that were evaluated as to cross-section were the multiplets at 1200 Å, 1493 Å and 1743 Å, although the data is available to determine the cross-sections for the other transitions.

Both the bands and the lines were evaluated identically. The shapes of the bands and lines were triangular since the instrumental width was greater than the natural width. Triangles were drawn over the bands and lines. The width and height of the triangle was measured and put on data cards. Each band was evaluated several times at 25 different energies, from 10 eV to 208 eV. The results for each band at each energy were averaged. The formula used for the determination of partial cross-section for the LBH bands was Eqn. 4.49, and for the nitrogen multiplets, Eqn. 4.68.

The absolute energy for the electrons as determined from the voltmeters was found to be in error by 2 $_{\pm}$ 0.5 volts since the LBH bands and the nitrogen lines were observed at 2 $_{\pm}$ 0.5 volts

TABLE 5.2

List of Observed Atomic Nitrogen Transitions

Wavelength	Multiplet
1200	⁴ s° - ⁴ P

1493	2 D $^{\circ}$ - 2 P
1743	² _P ° - ² _P

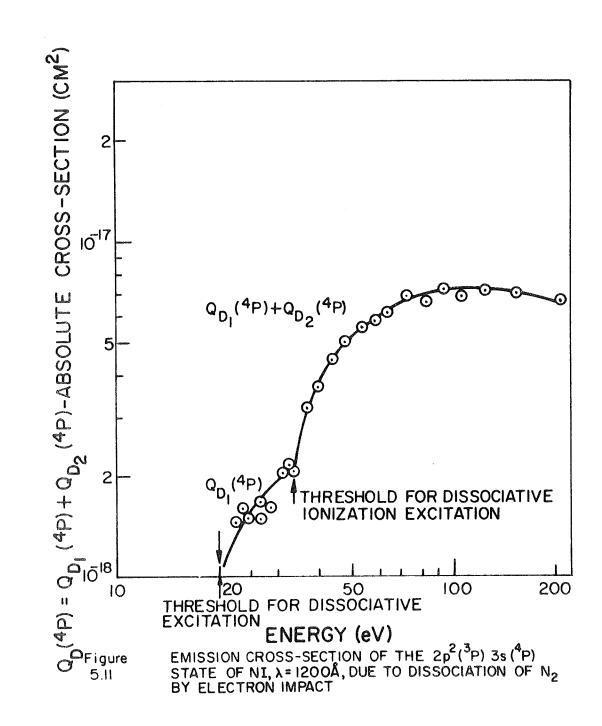

below the threshold as indicated by the voltmeters. The voltmeters were calibrated and could not be in error by this amount. Furthermore, by assuming a linear relationship between crosssection and energy near threshold, and extrapolating six bands to zero cross-section on a linear by linear plot, the intersection with the energy axis was determined to be at 2.5 ± 0.5 eV below the threshold. Two volts were added to all recorded accelerating voltages to determine the absolute energy scale. The absolute determination of energy is important at low energies where the cross-section is changing rapidly.

The effects that contribute spurious potentials to the indicated energy, in an electron beam experiment, are contact potentials between the electrodes in the electron gun and the space charge potential of the electron beam. The latter effect also causes a spread in energies of the beam. The effective energy resolution of the electron gun can be determined by considering this problem. Pierce (1954) has considered the effect of space charge in magnetically focused (Brillouin flow) and magnetically confined beams of axial symmetry. Due to space charge, the space potential inside the chamber is not uniform but assumes a distribution that decreases from the edge of the beam to the center of the beam. The potential gradient tends to move the electrons to the outside of the beam. A strong magnetic field constrains the motion. Using Pierce's

results for a magnetically confined beam 1 mm in diameter, an electron beam current of 150 microamps, an electron energy of 40 eV and a magnetic field of 160 gauss, a potential difference of approximately 0.9 eV from the center of the beam to the edge of the beam is obtained. Thus, in progressing from the center of the beam to the edge of the beam, there is a potential difference caused by the collective space charge of the electrons. Since the total energy of the electron, kinetic energy plus potential energy, is a constant equal to the accelerating energy, there is an effective spreading of the kinetic energy of the electrons across the beam of about 0.9 eV. The absolute energy scale is estimated to be accurate to \pm 1 eV.

5.5 Energy Dependence of the Emission Cross-Section of the Nitrogen Lines.

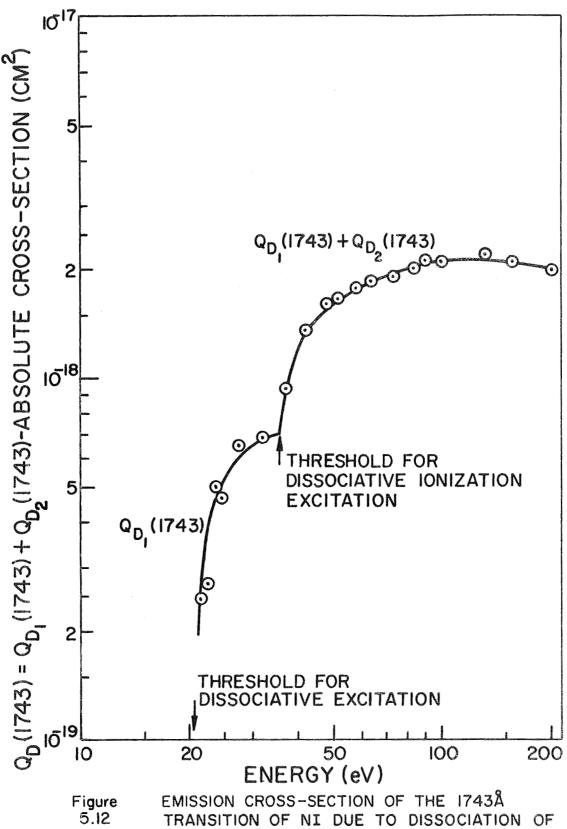

The emission cross-section, $Q_D(^4P)$, of the 4P state of NI due to dissociation of N_2 by electron impact is plotted in Figure 5.11. This cross-section was measured by experimentally determining the excitation function of the 1200 Å transition from the 4P state. The region between 20 eV and 35 eV corresponds to dissociative excitation of N_2 , and the region between 35 eV and 208 eV is the total cross-section of dissociative excitation plus dissociative ionization excitation. Both the dissociative excitation cross-section and the dissociative ionization excitation excitation cross-section rise very steeply from the threshold. The total cross-section reaches a peak

at about 110 eV and decreases very slowly to 200 eV. The 1200 Å line is thus the most intense individual feature in the electron excitation spectrum of N_2 in the wavelength region from 1200 Å to 2000 Å and for electron impact energies greater than 40 eV. It is observed from the shape of the cross-section curve that dissociative ionization excitation is the more important of the two processes above 50 eV.

The emission cross-section of the $\lambda=1743\,\text{\AA}$ transition, Q_D (1743), is displayed in Figure 5.12. Its shape is almost identical to that of the 1200 Å excitation function except it has a much lower cross-section. It, too, peaks at about 110 eV. Above 50 eV, dissociative ionization excitation is the dominant process. It represents a partial emission cross-section of the 2P state of atomic nitrogen and should make a contribution to the total cross-section of 26%. The 2P state decays by emitting the 1493 Å multiplet and 1743 Å multiplet in the ratio, .74 to .26. The energy level of the 2P state is about 0.4 eV higher than that of the 4P state.

The emission cross-section of the $\lambda=1493~{\rm \mathring{A}}$ transition, from excitation of molecular nitrogen by low energy electrons, is shown in Figure 5.13. This spectral feature is actually caused by two emissions at the same wavelength—one emission from the (3,3) LBH band and the other emission, at 1493 ${\rm \mathring{A}}$, from the ${}^2{\rm P} \rightarrow {}^2{\rm D}^{\rm O}$

N2 BY ELECTRON IMPACT

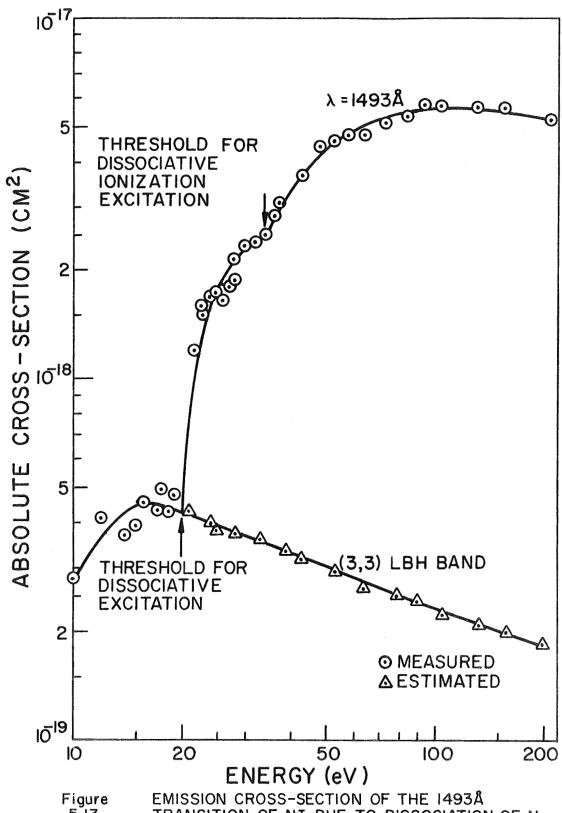

Figure EMISSION CROSS-SECTION OF THE 1493Å
5.13 TRANSITION OF NI DUE TO DISSOCIATION OF N2
+ EMISSION CROSS-SECTION (3,3) LBH BAND
BY ELECTRON IMPACT

transition of atomic nitrogen. Both transitions are excited from the ground state of molecular nitrogen. The 1493 Å line is the second most intense feature of the vacuum ultraviolet excitation spectra of N₂, for electron impact energies greater than 40 eV. Thus the excitation function of this transition shows three thresholds. The first at about 9.1 eV, the threshold for the v' = 3 level of the a $^1\Pi_g$ state. The next threshold is at about 20.5 eV, due to dissociative excitation of molecular nitrogen—one of the dissociation products being atomic nitrogen excited to the 2 P term. The final threshold is at 35.0 eV, from dissociative ionization excitation of molecular nitrogen.

The solid line of Figure 5.13 marked with triangles represents the estimated cross-section of the (3,3) band above 20 eV. The numbers were determined by taking the relative shape of the LBH cross-section of the next section and extrapolating the cross-section obtained below 20 eV to higher energies. For energies greater than 40 eV, the contribution of the (3,3) band to the total excitation cross-section becomes less than 10%. By subtracting the cross-section of the (3,3) band from the total cross-section, the emission cross-section, Q_D (1493), of the λ = 1493 Å multiplet of NI is determined. This cross-section is shown in Figure 5.14. It represents a partial emission cross-section of the 2 P

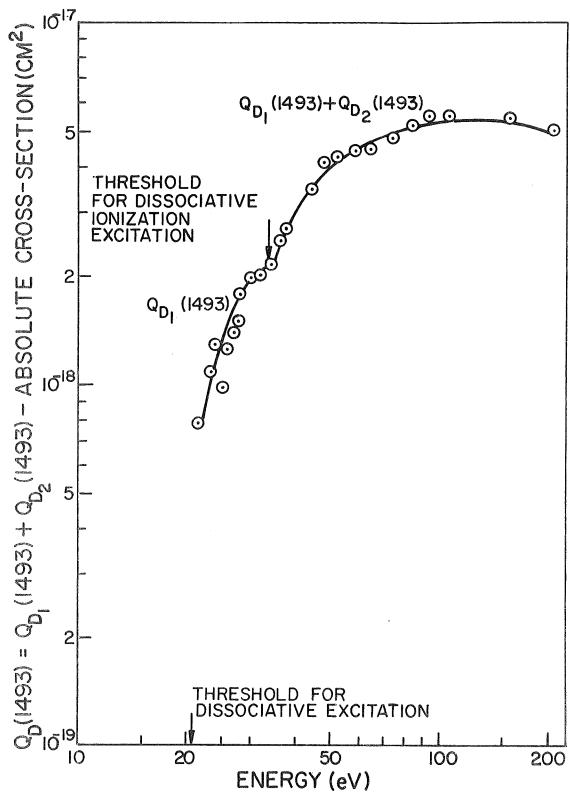

Figure EMISSION CROSS-SECTION OF THE 1493Å

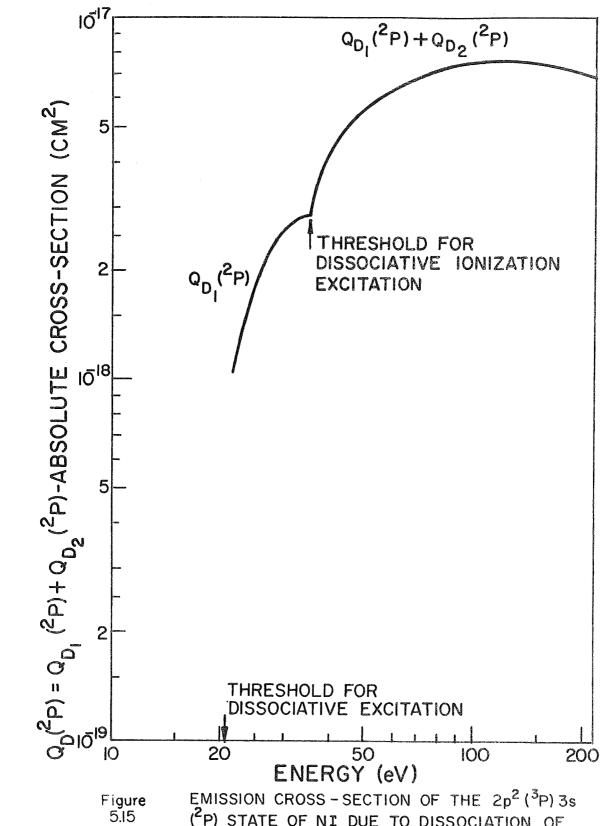

5.14 TRANSITION OF NI DUE TO DISSOCIATION OF N2
BY ELECTRON IMPACT

state of NI. The cross-section peaks at 110 eV, with a broad maximum from 70 eV to 200 eV. Both types of dissociative excitation cross-sections rise steeply from the threshold. Above 50 eV, dissociative ionization excitation is the predominant excitation process.

The total excitation cross-section, $Q_D(^2P)$, of the 2P state of NI, by dissociation of molecular nitrogen, is shown in Figure 5.15. The total cross-section of the 2P state, at 100 eV, is $7.78 \times 10^{-18} \text{ cm}^2$. The contribution at 100 eV from the 1493 Å transition is $5.68 \times 10^{-18} \text{ cm}^2$ and from the 1743 Å transition is $2.10 \times 10^{-18} \text{ cm}^2$. Thus the 1493 Å transition contributes 73% of the radiation, and the 1743 Å transition, 27%. So it is seen there is excellent agreement between the branching ratio calculation and the experiment as to the contribution of each transition to the total cross-section.

It is expected that the other nitrogen lines observed, as listed in Table 5.2, all have identical shapes as the three transitions measured. That is, the other nitrogen lines are almost certainly caused by dissociative excitation of $\rm N_2$.

As was mentioned in Chapter IV, there are other dissociation limits of molecular nitrogen that lie within a few eV of the first dissociation level of molecular nitrogen. In addition to the dissociation reaction that yields two ⁴S^o ground state nitrogen

(2P) STATE OF NI DUE TO DISSOCIATION OF N2 BY ELECTRON IMPACT

atoms, there are reactions that yield ${}^4S^{\circ}$ and ${}^2D^{\circ}$ nitrogen atoms, and also ${}^{4}S^{O}$ and ${}^{2}P^{O}$ nitrogen atoms. By analogy, it would be expected that dissociative excitation, in addition to yielding ⁴S^o and P nitrogen atoms and SO and P nitrogen atoms, would yield $^2\mathrm{D^O}$ or $^2\mathrm{P^O}$ and $^2\mathrm{P}$ nitrogen atoms and $^2\mathrm{D^O}$ or $^2\mathrm{P^O}$ and $^4\mathrm{P}$ nitrogen atoms. Thus there would be other dissociative excitation thresholds that would be denoted by an increase in cross-section, when the threshold is reached. It is not possible from this data to assess the importance of these additional possibilities. It would be necessary to have an electron gun with much finer energy resolution than that used here, and also to take measurement on a much finer energy scale of the order of tenths of eV apart in the threshold region. Furthermore, cross-sections are increasing so rapidly near threshold, it is difficult from these measurements to determine the importance of crossing these excitation thresholds. A similar argument applies to the dissociative ionization excitation process and also to the effects of cascading.

The total cross-section for dissociative ionization of molecular nitrogen by electron impact was measured by Englander-Golden and Rapp (1964). The peak cross-section was measured to be 6.4×10^{-17} cm² at an energy of 120 eV. The product ions were detected, if their kinetic energy was greater than 0.25 eV. In this experiment, both the effects of dissociative ionization and

dissociative excitation were summed. It appears that dissociative ionization excitation is the predominant process. If, as a lower limit, it is assumed at a 110 eV that half the cross-section of the nitrogen emission lines is from dissociative ionization, then the total cross-section in the vacuum ultraviolet, due to dissociative ionization is about 7×10^{-18} cm² for the three lines measured, and about 3×10^{-18} cm² for the other nitrogen lines of Table 5.2. Thus, in the dissociative ionization process measured by Englander-Golden and Rapp (1964), at least 15% of the nitrogen atoms produced are in highly excited states.

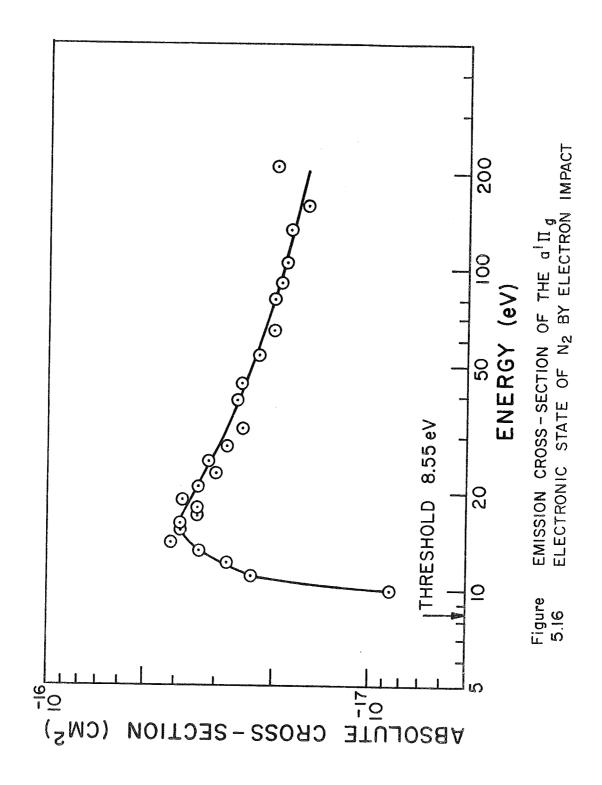

Furthermore, the total dissociative ionization cross-section falls by a factor of 0.36 from peak to 1 keV. One would expect the dissociative ionization excitation process to fall in about the same proportion. Thus the dissociative ionization cross-section falls slowly with increasing energy.

5.6 Energy Dependence of the Emission Cross-Section of the a $^{1}\Pi_{_{\mathbf{G}}}$ State.

The total measured emission cross-section of the LBH transition by electron impact is shown in Figure 5.16. It is defined as

$$Q_{LBH} = {}^{6}\Sigma_{V'=0} Q_{OV'}$$
 (Eqn. 4.46)

Each of the individual Q_{OV} are in turn illustrated in Figures 5.17

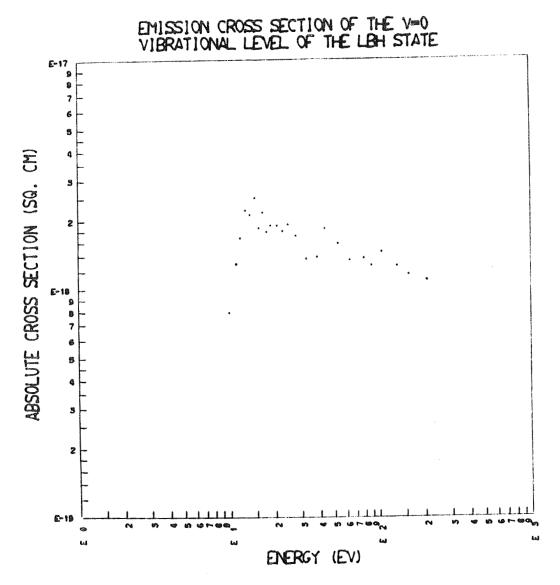

Figure 5.17

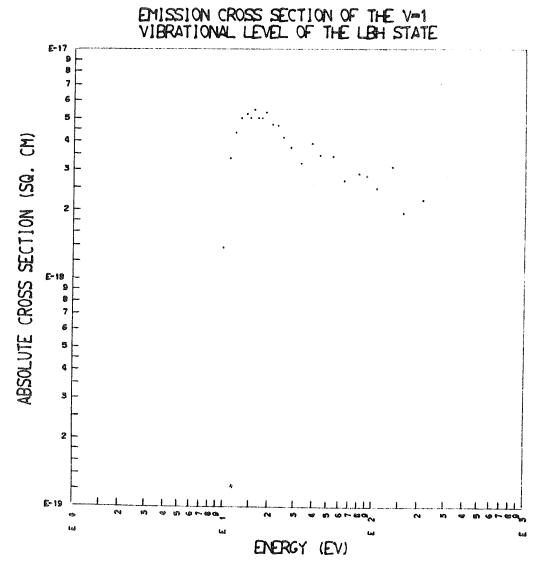

Figure 5.18

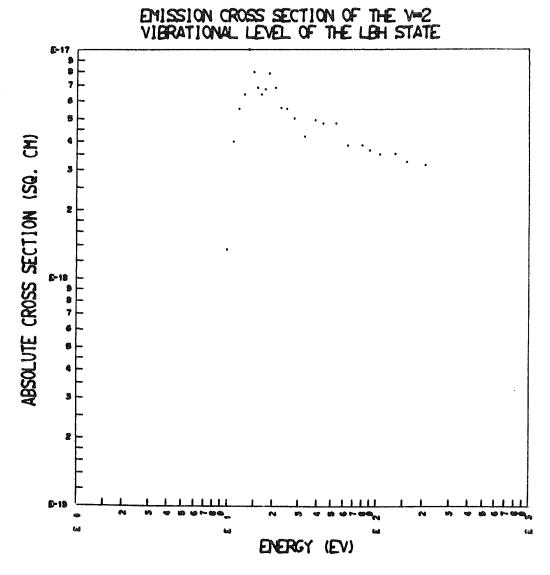

Figure 5.19

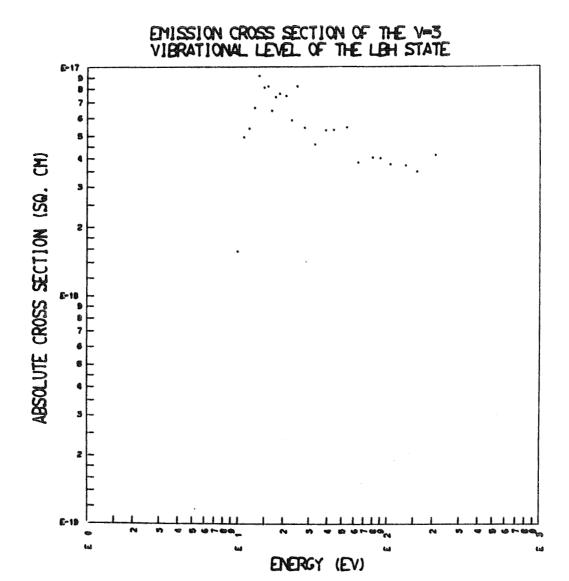

Figure 5.20

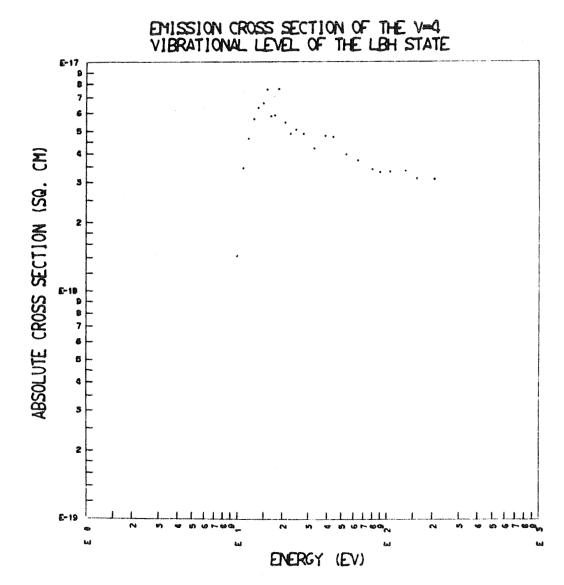

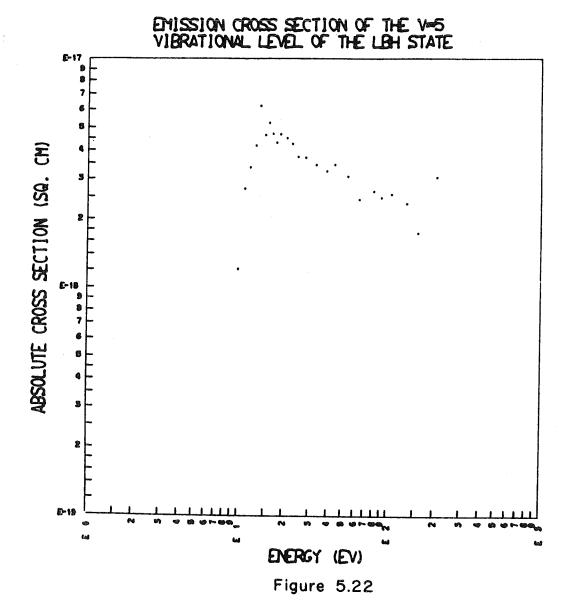

Figure 5.21

EMISSION CROSS SECTION OF THE V=6 VIBRATIONAL LEVEL OF THE LBH STATE

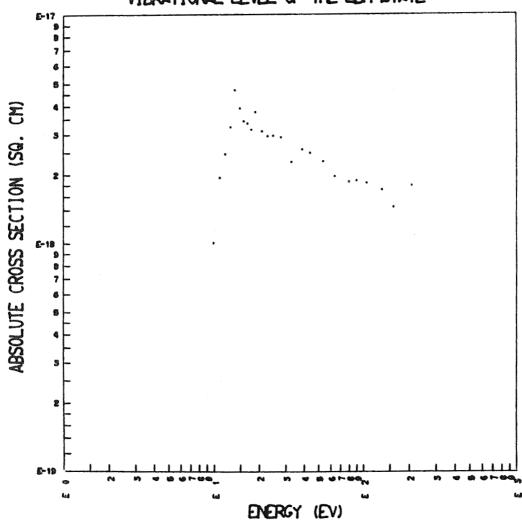

Figure 5.23

to 5.23. Each of the $Q_{OV'}$ are defined from the equation

$$Q_{ov'} = \Sigma_{v''} Q_{v'v''} ,$$

that is, as a sum of band emission cross-sections. These band emission cross-sections, which represent the actual experimental data points, are depicted in Appendix B.

The peak total cross-section is at 15.5 ± 1.5 eV with a broad maximum between 14 eV and 19 eV. The total cross-section, at peak, is 3.85×10^{-17} cm² and at 105 eV is 1.90×10^{-17} cm². The shape of the cross-section curve agrees very well with the shape predicted by Green and Barth (1965), although the peak cross-section occurs at about 3 eV lower energy. The absolute values predicted by Green and Barth agree to within 15% to the experimentally measured cross-section.

The results for the total LBH cross-section agree very well with the inelastic cross-section measurement for electrons in nitrogen by Engelhardt, Phelps and Risk (1964). The cross-section for excitation to the a $^{1}\Pi_{\rm g}$ state was measured in an electron swarm experiment by solving the Boltzman equation for the distribution function of electron energies in a neutral gas. The peak cross-section at 9.1 eV was 4.1 x $10^{-17}~{\rm cm}^{2}$.

The results also compare reasonably well with the theoretical predictions of Rozsnyai (1967). Rozsnyai calculated a

peak value for the absolute cross-section of 2.6 x 10^{-17} cm² at about 18 eV for excitation to the a $^{1}\Pi_{g}$ state, using the first Born approximation for homonuclear diatomic molecules. The results presented here show a peak emission cross-section of 3.85 x 10^{-17} cm². Thus there is about a 33% difference. Part of the difference could be from a cascade contribution, although the cascade contribution to the emission cross-section is felt to be small.

However, the results differ significantly from the experimental results of Holland (1969). At 105 eV, for example, the total measured cross-section is a factor 2.8 larger than that measured by Holland. In this experiment, as well as in Holland's, there is excellent agreement between theory and experiment as to the fraction of the total cross-section contributed by each vibrational level. For the LBH transition, it is expected that

$$\frac{Q_{OV'}}{\sum_{V'} Q_{OV'}} = \frac{q_{OV'}}{\sum_{V'} q_{OV'}}.$$

At 105 eV the ratio of $Q_{\rm OV'}$ to $Q_{\rm LBH}$ was calculated and compared to the ratios predicted by the Franck-Condon factors for direct electron excitation of the various vibrational levels. The results are presented in Table 5.3. The agreement is very good and implies most of the excitation is due to direct electron impact. It is observed that the v'=3 vibrational level has the largest cross-section in agreement with the Franck-Condon factors.

Since the electron resolution of the electron gun is of the order of 1 eV and the intensity of the individual bands very small, it was not possible to determine with accuracy if there was a cascade contribution onset. Furthermore, the cross-section curve is rising very steeply from threshold. If it is assumed that the total change in cross-section from 12 eV to 15.5 eV is from cascading, then the maximum cascade contribution (slow cascade plus fast cascade) is 29%, since the total cross-section is 2.73 x 10^{-17} cm^2 at 12 eV and 3.85 x 10^{-17} cm^2 at 15.5 eV. The actual cascade contribution should be much less since most of the increase in cross-section from 12 eV to 15.5 eV is probably by direct electron excitation of the $a^1\Pi_{\alpha}$ state. To determine with accuracy the contribution of cascade, a very careful study of the cross-section as a function of energy near threshold would have to be made. It would require an electron gun with higher energy resolution then the one used in the experiment. Either this approach or the approach of looking for the cascade radiation in the region of 2000-3000 Å region would have to be adopted to determine the amount of cascading and, further, if there is a cascade which is slow, to determine its effect on the 80 microsecond lifetime, as measured by Holland. In Appendix B are shown the experimentally measured cross-sections for the most prominent LBH bands. In these data any bands that were overlapped were separated out, assuming the validity of

using the Franck-Condon factors for direct electron excitation. The bands separated out are listed in Table 5.1. Thus the actual data for these bands is a sum of the two overlapped bands. The most prominent LBH band features are the (4,0) band at 1325 Å, the (3,0) band at 1353 Å, the (5,2) band and (2,0) band at 1383 Å, the (2,1) band at 1429 Å and the (1,1) band at 1464 Å. Of these individual bands, the (3,0) band at 1353 Å has the largest excitation cross-section. Within the experimental error, each band has the same relative shape. This result is consistent with the expermental results of McEwen (1965), Lassettre, et al. (1968), and Holland (1969).

Two bands that were extremely weak were the (8,0) and (8,1) band. It is of interest to mention these bands since they have not been observed previously in electron beam excitation experiments. In fact, the v'=8 vibrational level is in the predissociation region of the $a^1\Pi_g$ state, which accounts for its small excitation crosssection. The results on these bands were uncertain. The measured points are shown in Appendix B.

There is some indication that the (7,0) band at 1249 Å may be present in the wing of the 1243 NI line. If it is present it has an extremely small cross-section. less than that of the (8,0) and (8,1) band. The v'=7 and v'=8 vibrational levels were not

included in the total cross-section calculation due to the large uncertainity of their individual cross-sections. The total cross-section of the v'=7 and v'=8 vibrational levels is less than 3% of the total LBH cross-section.

5.7 Polarization.

Two types of transitions have been studied, one is the excitation of the a $^{1}\Pi_{g}$ state of molecular nitrogen and the other is the dissociative excitation of molecular nitrogen. In this section it is intended to show the polarization effects on the cross-section are small. No measurements of polarization were made.

First, consider the dissociative excitation of N_2 in an electron beam experiment. The target molecule is subjected to impact by electrons having a preferred direction of incidence. Van Brunt and Zare (1968) have shown that two necessary conditions for polarization are: (a) an anisotropic spatial distribution of dissociation products, and (b) a preferential population of the magnetic sublevels of the excited fragments. These conditions are satisfied when dissociation proceeds via a single, well defined potential curve. In this case, the atoms depart from one another in well defined M states, with respect to the internuclear axis. Further, the distribution of the quantization axis is nearly the same as the angular distribution of the products. In a recent experiment, Kieffer and Van Brunt (1967) report a nearly isotropic angular distribution of

 $\ensuremath{\text{N}^{+}}$ ions in studying the dissociative ionization of $\ensuremath{\text{N}}_2$. This is presumably due to the fact that many repulsive states of N_2 contribute to the dissociation. In the previous discussion of dissociation in section 4.4.2, it was only necessary to develop the concept of dissociation by considering one potential curve. When two atoms are placed near each other, an inhomogeneous electric field is produced along the direction joining the nuclei. Thus, two atoms brought together form a manifold of electronic molecular states having well defined projections of their angular momenta on the internuclear axis. Conversely, when these same two atoms separate via a repulsive state, they leave each other in well defined M states with respect to the internuclear axis. When two nitrogen atoms, or a nitrogen ion and nitrogen atom, in definite electronic states, are brought together, a whole series of states result, depending on the orientation of $\mathbf{L}_{\mathbf{i}}$ the orbital angular momentum, with respect to the internuclear axis. Molecular dissociation is an efficient M state selector only if one or a limited number of states, contribute to the dissociative process. Undoubtedly in the case of N_2 , many states contribute to the dissociation, washing out the polarization effect.

For the LBH bands, it is expected the conditions for polarization are greatest near the threshold region where the direction of the electron beam, the direction of the magnetic field and the direction of the momentum transfer vector are all very close to one another. Thus there is a space quantization of the total angular momentum of the molecule. The rotational levels of the molecule characterized by J, splits into 2J + 1 sublevels. The polarization of radiation emitted in a transition from a state of definite orbital angular momentum can be expressed in terms of the cross-sections for exciting the various magnetic substates. As an approximation, assume the cross-section for exciting the various sublevels are proportional to the transition probability for exciting the sublevel. This is a very crude approximation in the threshold region, but a detailed analysis of polarization by electron impact is beyond the scope of this thesis. Then the polarization formulas are the same as for molecular fluorescence, when a beam of linearly polarized light is incident upon a collection of randomly oriented molecules in the gas phase. This problem has been solved by Zare (1966). Formulae are given for polarization for the P, Q and R branches. Polarization calculations, using Zare's results, indicate a 'worst case' degree of polarization of about 30%. This percentage introduces an uncertainty of about 10% in the cross-section measurement near the threshold. For dipole radiation and observations at 90° to the beam, it can be shown (Moiseiwitch and Smith, 1968)

$$\bar{I}' = I' (90^\circ) [1 - \frac{P}{300}],$$

where:

- I' is the average intensity of radiation resulting from averaging the intensity over a sphere,
- P is the percentage of polarization,
- I'(90°) is the intensity at 90° to the beam.

The percent of polarization varies from 10% to 30%, depending on the sequence involved in exciting a rotational line. For example, an orbital electron can go to an excited state via a Q branch and emit radiation in a P branch. In all, there are nine possibilities affecting the angular distribution of the spontaneous radiation. In this experiment, rotational structure was not resolved. The net effect of resolving just vibrational structure was to sum over the rotational transitions and remove most of the anistropy.

It is expected that the degree of polarization decreases rapidly as the electron beam energy increases above threshold. This arises from the fact the momentum transfer vector is no longer oriented along the beam axis, but will be at an angle to it. In this case, the resultant angular momentum vector precesses about the magnetic field and results in a disorientation of the radiators.

5.8 Error Analysis.

The major uncertainties in the measurements arise from the uncertainties in the following parameters: absolute calibration, relative calibration, pressure, transition probability of the LBH state,

relative cross-section, and photomultiplier current measurements with the picoammeter-Brush recorder combination. The uncertainties discussed in the section are: estimated root mean square deviations, as determined from either repeatability measurements, manufacturer's specifications, or from experimental work of other authors. The uncertainties for these parameters were determined as follows:

- Absolute Calibration: The absolute calibration uncertainty was determined by taking each of the quantities of Eqn. 3.7 and assigning experimental uncertainties to each parameter. These uncertainties included the uncertainty in the NO quantum efficiency, 5% (Samson, 1967); the uncertainty in the transmission of the lithium fluoride window, 1%; the uncertainty of the two current measurements, 3% each; the drift of the lamp, 3%; and the noise in the NO cell, 3%.
- Relative Calibration: There is a 10% uncertainty in the efficiency of the monochromator because of the different experimental conditions present during the calibration and experiment. There is a 5% uncertainty in the repeatability of the efficiency measurement during calibration. This number was obtained by taking an average of the experimental points at each wavelength and then determining a root mean

square deviation from the average. The uncertainty in the relative calibration of the 541G photomultiplier is due to a 3% uncertainty in the experimentally averaged points and a 3% uncertainty in the relative response of sodium salicylate.

- 3) <u>Pressure Calibration</u>: There is a 5% uncertainty in the absolute calibration method.
- The Transition Probability of the LBH State: There is an uncertainty of a factor of 2 in the transition probability which leads to an approximate 10% uncertainty in the fraction of the LBH radiation collected.
- Relative Cross-Section: The uncertainty in the shape of the relative cross-section curve for the LBH bands is primarily from the scatter of experimentally measured points (Appendix B). By fitting many of the experimentally measured emission cross-section points of each individual band with the shape of the LBH curve, as determined for the total LBH electronic transition, an approximate uncertainty for the root mean square deviation of the individual experimental points from the true value was determined. The value was 8% for the stronger bands, $1273 < \lambda < 1600 \text{ Å}$, and 16% for the weaker bands, $1600 < \lambda < 1962 \text{ Å}$. The average

value used for the uncertainty was 12%. For the atomic nitrogen lines, by a similar procedure, the value was 3%.

The Current in the Photomultiplier with a Picoammeter
Brush Recorder Combination: There is a 3% uncertainty in the repeatability of the current measuring
combination, according to the manufacturer specifications.

The resultant root mean square deviation or uncertainty in the absolute emission cross-section because of each of these independent, ramdom effects is 22% for the LBH bands and 16% for the nitrogen lines.

The large scatter of points in the case of the LBH bands was caused by the low intensity of radiation emitted by each individual band. The signal to noise ratio was much less than in the case of the atomic nitrogen lines. Therefore it was more difficult to accurately determine the area under each band, the weaker the band.

For the more intense LBH bands, that is, for the bands with the largest emission cross-section, there was very little scatter of the individual points. These bands include the (5,0), (4,0), (3,0), (2,0) and (1,1). In order not to rely totally on Franck-Condon factors for the determination of cross-section, all transitions from the

LBH state were measured experimentally except for about 5% of the transition from 1962 Å to 2300 Å. For the region from 1600 Å to 1900 Å, which contained the weaker bands and also the minimum response of the optics, the scatter was appreciable. The best results for the LBH system was the region 1273 Å to 1600 Å, which contained the strongest bands and also maximum response of the system. Because of the laws of statistics which states the distribution of experimental points are Gaussian about the true mean value, the effect of adding all the emission corss-sections at a particular energy to form the total cross-section filtered out most of the uncertainty in the shape of the total cross-section curve. Furthermore, since the most intense bands had a larger partial cross-section and smaller uncertainty in its absolute value, these cross-sections had a larger weight of the total cross-section.

CHAPTER VI

ATMOSPHERIC APPLICATIONS

6.1 Introduction

Two of the most important atmospheric applications of these measurements are the calculations of emission rate factors in the dayglow and aurora by electron impact. Both the Lyman-Birge-Hopfield band system and the atomic nitrogen lines have been observed in the aurora (Fastie, 1967) and in the dayglow in the recent Bushmaster rocket flights (Barth, 1969) conducted by the Laboratory for Atmospheric and Space Physics. In the aurora, the main excitation mechanism for the LBH bands is the low energy secondary electrons. The secondary electrons are produced by ionization of the atmospheric constituents by a primary electron flux in the energy range 500 eV to 10 keV. The excitation of the nitrogen lines, being primarily an ionization process, is caused both by the primary and the secondary fluxes. This stems from the fact the ionization cross-sections for the nitrogen lines are still relatively large in the primary energy range, while the production of the LBH bands is mainly determined by the secondary electron flux.

The dayglow consists of spectral features that occur in the upper atmosphere when it is directly illuminated by solar

radiation. The phenomena that produce these emission features are resonant and fluorescent scattering of solar radiation, chemical and ionic reaction and photoelectron excitation of atoms and molecules. It is the last of these phenomena for which the emission crosssection measurements have application. The photoelectrons are produced in the process of ionization of atoms and molecules by extreme ultraviolet solar radiation. The effects of secondary electrons, which are produced by further ionization of the atmospheric species by the primary photoelectrons, are negligible in the dayglow for the N_{2} ultraviolet features, since the mean secondary electron energy is about 5 eV (Green and Barth, 1967). The main excitation mechanism in the dayglow for the LBH bands is the photoelectron mechanism. For the atomic nitrogen lines, photodissociation and photoionization of ${\rm N}_2$ may be important. Because of the unavailability of photodissociative excitation cross-sections and photoionization excitation cross-sections, it is not possible to predict the amount of dayglow radiation produced by the effect. The calculation of the intensities of the atomic nitrogen lines by assuming only photoelectron mechanism represents a lower limit. By a comparison with a measurement of intensity by rocket measurements, it would be possible to determine if the other excitation mechanism needs to be considered.

In this chapter the emission rate factor is calculated for the LBH band system and the atomic nitrogen lines in the dayglow as a function of slant column density of the atmosphere. The slant

column density is the integeral of the number density between the observer and the Sun. The computation uses the results of Dalgarno, McElroy and Stewart (1969) who have calculated steady state primary photoelectron electron fluxes for a zenith angle of 72°. The calculation of emission rate factors presented here provides a method of determining volume emission rates for these emission features in the dayglow for any model atmosphere or zenith angle.

A calculation of the emission rate factor in an auroral oval is made using the computation of secondary electron fluxes of Rees (1969).

6.2 The Dayglow.

Photoelectrons are produced by the ionizing solar radiation between 31 Å and 1027 Å. The solar spectrum in this region has been measured by Hinteregger, Hall and Schmidtke (1964). They have tabulated the flux in the region, $\lambda < 1775$ Å, at wavelengths fo 24 major spectral lines and in 67 zones of the continuum.

For photons of wavelength λ , the rate of production of primary photoelectrons in the i-th ionization state of the k-th atmospheric species, having particle density n_k (z) is

$$C_{ik}(\epsilon,z,\chi) = Q_{ik}(\lambda) n_k(z) F(\lambda,z,\chi) , \qquad (6.1)$$

where:

 $I^{Q}_{\dot{1}\dot{k}}$ (λ) is the i-th ionization cross-section of the k-th species by photons of wavelength λ ,

- $n_k(z)$ is the number density of the k-th atmospheric constituent at altitude z,
- F(λ,z,χ) is the solar flux at altitutde z, zenith angle χ and wavelength λ . The solar XUV flux also depends on the solar cycle.

The energy of the photoelectron produced in this particular reaction is given by

$$\epsilon_{ik} = \frac{hc}{\lambda} - I_{ik} . \qquad (6.2)$$

 I_{ik} is the ionization potential of the i-th state of species k.

Thus, incident photons of a single energy generates photoelectrons with a set of energies determined by the ionization thresholds of each atmospheric species. Alternatively, a set of wavelengths, defined by hc/ λ - I_{ik} = constant, generates photoelectrons of a single energy. The solar flux at any altitute and for zenith angle χ (χ < 80°) is given by

$$F(\lambda, z, \chi) = F_{O}(\lambda) .$$

$$\exp \left[-\sec \chi \sum_{m} A^{Q}_{m}(\lambda) \int_{z}^{\infty} n_{m}(y) dy\right], \quad (6.3)$$

where $\sec \chi$ is an approximation to the Chapman function.

$$\int_{Z}^{\infty} n_{m}(y) dy = \eta_{m}(z) , \qquad (6.4)$$

where:

 $_{\text{A}}^{\text{Q}}_{\text{m}}\left(\lambda\right)$ is the total absorption cross-section of the m-th species at wavelength λ , and

 $\eta_{\rm m}$ (z) is the column density of the m-th species. Combining equations 6.1, 6.3 and 6.4, the production rate of photoelectrons of energy $\epsilon_{\rm ik}$ by the i-th ionization state of the k-th species is

$$C_{ik}(\lambda, y, \chi) = F_{O}(\lambda) I_{Q_{ik}}(\lambda) n_{k}(z).$$

$$\exp \left[-\sec \chi \sum_{m} Q_{m}(\lambda) \eta_{m}(z)\right]. \qquad (6.5)$$

The total production rate of primary photoelectrons of energy ϵ , created by photoionization, is a sum over i and k such that

$$\epsilon = \frac{hc}{\lambda} - I_{ik}$$
.

Thus,

$$C(\epsilon, z, \chi) = \Sigma_i \Sigma_k$$
.

$$F_{o} \left(\frac{hc}{\epsilon + I_{ik}} \right) I^{Q}_{ik} \left(\frac{hc}{\epsilon + I_{ik}} \right) .$$

$$n_{k}(z) \exp \left(-\sec \chi \sum_{m} A^{Q}_{m} \left(\frac{hc}{\epsilon + I_{ik}} \right) \eta_{m}(z) \right) .$$

$$(6.6)$$

Define $S_{ik}(\epsilon,z,\chi)$ as

$$S_{ik}(\epsilon, z, \chi) = F_{o}\left(\frac{hc}{\epsilon + I_{ik}}\right) I^{Q}_{ik}\left(\frac{hc}{\epsilon + I_{ik}}\right).$$

$$\exp \left(-\sec \chi \sum_{m} \sum_{A} Q_{m} \left(\frac{hc}{\epsilon + I_{ik}}\right) \eta_{m}(z)\right) . \qquad (6.7)$$

This quantity is the number of photoelectrons produced per second of energy ϵ at altitude z per molecule with solar illumination at zenith angle χ in the i-th ionization state of the k-th constituent.

The total photoelectron production rate at energy ϵ is

$$C(\epsilon,z,\chi) = \sum_{ik} n_k (z) S_{ik}(\epsilon,z,\chi) \frac{\text{electrons}}{\text{cm}^3 \text{ sec}}$$
 (6.8)

The steady-state photoelectron flux is (Dalgarno et al., 1969)

$$\Phi(\epsilon, z, \chi) = \frac{\sum_{\epsilon_{j} > \epsilon} C(\epsilon_{j}, z, \chi)}{\sum_{\ell} n_{\ell} L_{\ell}(\epsilon)} \frac{\text{electron}_{s}}{\text{cm}^{2} \text{sec eV}}, \quad (6.9)$$

where L_{ℓ} (ϵ) is the total loss function for the ℓ -th constituent in units of eV cm². It describes the total energy loss of the photoelectrons to all processes. The assumption of continuous energy loss is made. This is an approximation which is adequate for $\epsilon > 8$ eV. The assumption is also made that the photoelectrons interact locally. This is satisfactory at altitudes less than 250 km, where most of the dayglow emission occurs.

Dalgarno, McElroy and Stewart (1969) have used the solar fluxes of Hinteregger, Hall and Schmidtke (1964) to calculate the equilibrium photoelectrons fluxes at various altitudes for a solar zenith angle of 72° and for a model atmosphere with an exospheric

temperature of 750 °K. Their calculations assumed a continuous energy loss for the photoelectrons. The photoelectron flux as a function of energy is, on the average, a decreasing function as energy increases. The emission cross-section of the LBH bands is a decreasing function of energy past 15.5 eV. Thus, the excitation of the LBH bands is caused for the greater part by electrons in the 8.55 eV to 30 eV range. With a knowledge of the photoelectron fluxes it is straightforward to write an expression for the volume emission rate for the j-th excitation level of the k-th species. Deactivation is negligible for the N₂ transitions being considered above an altitude of 120 km, so that the volume excitation rate is equal to the volume emission rate. Thus, the volume emission rate is

$$I_{jk}(z,\chi) = n_{k}(z).$$

$$\int_{\epsilon_{T}}^{\infty} \Phi(\epsilon,z,\chi) Q_{jk}(\epsilon) d\epsilon \left(\frac{\text{photons}}{\text{cm}^{3} \text{ sec}}\right), \qquad (6.10)$$

where:

 ϵ is the energy of the photoelectron,

 $\epsilon_{\,\mathrm{T}}$ is the threshold energy for process j,

 Q_{jk} is the emission cross-section of the j-th state of the k-th species.

The emission rate factor, g_{ik} , for the photoelectron excitation

of the j-th transition of the k-th species is defined as

$$g_{jk}(z,\chi) = \int_{\epsilon_T}^{\infty} \Phi(\epsilon,z,\chi) Q_{jk}(\epsilon) d\epsilon \left(\frac{\text{photons}}{\text{sec molecule}}\right)$$
 (6.11)

A plot of the results of Dalgarno, McElroy and Stewart is shown in Figure 6.1. It is obvious from these curves that $\Phi(\epsilon, z, \chi = 72^{\circ})$ can be written with sufficient accuracy (within 15%) as

$$\Phi(\epsilon, z, \chi = 72^{\circ}) = \Phi_{O}(\epsilon) f(z, \chi = 72^{\circ}) \text{ for } \epsilon > 8 \text{ eV}$$
 (6.12)

and over the altitude range 120 to 300 km, where $\Phi_{\rm O}$ is the photoelectron flux at 300 km.

Thus,

$$g_{jk}(z, \chi = 72^{\circ}) = g_{0jk} f(z, \chi = 72^{\circ}),$$
 (6.13)

where

$$g_{O_{jk}} = \int_{\epsilon}^{\infty} \Phi_{O}(\epsilon) Q_{jk}(\epsilon) d\epsilon$$
.

 $f(z,\chi)$ is a function of both altitude and solar zenith angle. It is equal to 1 at 300 km.

$$f(z,\chi) \equiv e^{-\alpha(z)} \eta_{\chi}(z) , \qquad (6.14)$$

where

$$\eta_{\chi}(z) = \sec \chi \int_{z}^{\infty} \sum_{k} n_{k}(y) dy.$$
(6.15)

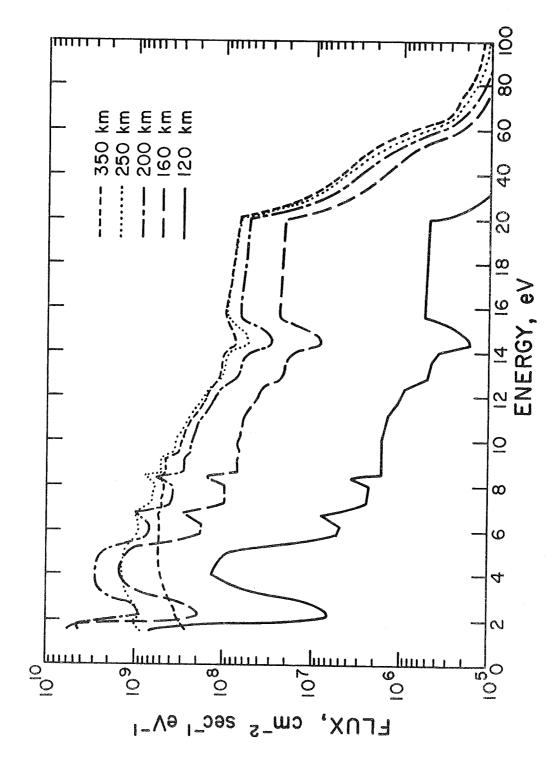

Figure 6.1 EQUILIBRIUM PHOTOELECTRON FLUXES ϕ (E) AS A FUNCTION OF ENERGY AT VARIOUS ALTITUDES. NOTE THE CHANGE IN THE HORIZONTAL SCALE AT 20 eV

Thus, η_{χ} (z) is the total slant column density of the atmosphere between level z and the Sun. $f(z,\chi)$ is defined this way, since the change with altitude of photoelectron flux is primarily due to absorption of the solar XUV radiation by the atmospheric constituents. α is a function of altitude, since the relative composition of the atmosphere is changing with height, thus absorbing the solar radiation in a manner that depends on altitude. This definition of $f(z,\chi)$ is equivalent to the following approximation in Eqn. 6.6:

$$\sum_{m} A^{Q_{m}} \left(\frac{hc}{\epsilon + I_{ik}} \right) \eta_{m}(z) = \alpha(z) \sum_{m} \eta_{m}(z) \qquad (6.16)$$

where α is an effective absorption. With this approximation it is now possible to separate S_{ik} into a product of functions, one dependent on energy, the other on slant column density. α is the effective cross-section for the solar flux at altitude z. It is an average with respect to wavelength over the XUV spectral region weighted by the column density of each species between the observer and the top of the atmosphere. It is determined empirically and is justified by the fact the quantity α reproduces the effect of the atmospheric absorption on the solar XUV radiation as far as it determines the photoelectron flux. Separating S_{ik} into two functions, one dependent on energy, B_{ik} (ϵ), and the other an exponential function of slant column density, it is found that

$$S_{ik}(\epsilon,z,\chi) = B_{ik}(\epsilon) \exp \left[-\alpha \sec \chi \sum_{m} \eta_{m}(z)\right]$$
(6.17)

where

$$B_{ik} = F_0 \left(\frac{hc}{\epsilon + I_{ik}} \right) I_{ik} \left(\frac{hc}{\epsilon + I_{ik}} \right).$$

 B_{ik} is the number of photoelectrons produced per second at the top of the atmosphere by ionization process (i,k). The total photoelectron production rate at energy ϵ is

$$C(\epsilon, z, \chi) = \exp \left(-\alpha \sec \chi \sum_{m} \eta_{m}(z)\right) \sum_{ik} n_{k} B_{ik}(\epsilon)$$
 (6.18)

or

$$C(\epsilon, z, \chi) = \exp -\alpha \sec \chi \sum_{m} \eta_{m} \sum_{k} n_{k} B_{k}(\epsilon)$$
 (6.19)

where

$$B_{k}(\epsilon) = \sum_{i} B_{ik}(\epsilon) . \qquad (6.20)$$

Define

$$\bar{B}(\epsilon) = \frac{\sum_{k}^{\infty} n_{k} B_{k}(\epsilon)}{\sum_{k}^{\infty} n_{k}}, \qquad (6.21)$$

where

$$\sum n_k = N$$
.

N is the total number density.

Then,

$$C(\epsilon, z, \chi) = N \bar{B}(\epsilon) \exp \left(-\alpha \sec \chi \sum_{m} \eta_{m}(z)\right)$$
 (6.22)

An energy loss function for the atmosphere at any given altitude can be defined by

$$L(\epsilon) = \frac{\sum_{k}^{\Sigma} n_{k} L_{k}(\epsilon)}{\sum_{k}^{\Sigma} n_{k}}.$$
 (6.23)

Thus,

$$\Phi(\epsilon, z, \chi) = \frac{N \exp \left[-\alpha \sec \chi \sum_{m} \eta_{m}(z)\right] \sum_{\epsilon_{j}} > \epsilon}{N L(\epsilon)}$$
(6.24)

or dividing the numerator and denominator of Eqn. 6.24 by N, it is seen that

$$\Phi(\epsilon, z, \chi) = \exp[-\alpha \sec \chi \sum_{m} \eta_{m}(z)] \frac{\sum_{\epsilon_{j} > \epsilon} B(\epsilon_{j})}{L(\epsilon)} . (6.25)$$

Thus, Φ in this approximation is a product of two functions, where:

$$\Phi_{O}(\epsilon) = \frac{\sum_{\epsilon_{j} > \epsilon} B(\epsilon_{j})}{L(\epsilon)}$$
(6.26)

and

$$\eta_{\chi} = \sec \chi \sum_{m} \eta_{m}$$
 (6.27)

Substituting these two equations into Eqn. 6.25, it is found that

$$\Phi(\epsilon, z_{,\chi}) = \Phi_{0}(\epsilon) \exp[-\alpha \eta_{\chi}] , \qquad (6.28)$$

and hence

$$g_{jk}(z,\chi) = \exp[-\alpha \eta_{\chi}] \int_{\epsilon_T}^{\infty} \Phi_{o}(\epsilon) Q_{jk}(\epsilon) d\epsilon$$
 (6.29)

or,

$$g_{jk}(z,\chi) = g_{0jk} \exp[-\alpha \eta_{\chi}]$$
,

where

$$g_{o_{jk}} = \int_{\epsilon_{T}}^{\infty} \Phi_{o}(\epsilon) Q_{jk}(\epsilon) d\epsilon$$
.

A semi-log plot of g versus η_{χ} for the LBH bands and nitrogen lines is shown in Figure 6.2. It is a straight line for slant column densities less than 7 x 10 17 particles/cm 2 . The altitudes corresponding to

$$\eta_{\chi} = \sec 72^{\circ} \int_{Z}^{\infty} n(z) dz$$

are shown for the particular model atmospheres of the Dalgarno, et al., calculation. If it is assumed that the emission rate factor depends only on the slant column density, then the plot of g versus η_χ is a good approximation to the emission rate factor for other model atmospheres with the same boundary conditions for the major atmospheric constituents as used in the calculation of Dalgarno, McElroy and Stewart, and for all zenith angles (sec χ becomes the Chapman function for $\chi>80^\circ$), although g is calculated for a solar zenith angle of 72 $^\circ$ and a model atmosphere of 750 $^\circ$ K exospheric temperature. Thus, if η_χ is calculated for the conditions of a particular observation, the emission rate factor can be read from Figure 6.2.

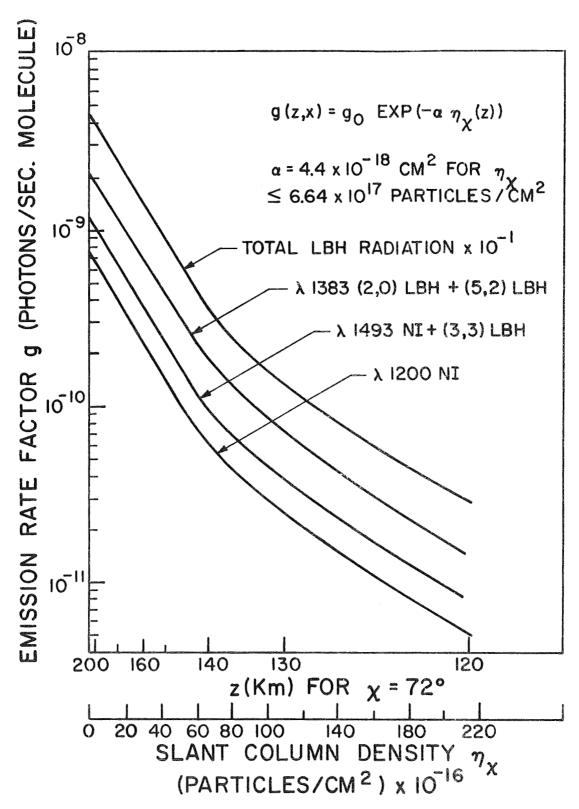

Figure 6.2 EMISSION RATE FACTOR, g, AS A FUNCTION OF SLANT COLUMN DENSITY (TOTAL ATMOSPHERIC COLUMN DENSITY BETWEEN OBSERVER AND SUN) FOR EXCITATION OF N₂ BY PHOTOELECTRONS

If lpha is regarded as an effective absorption coefficient of solar XUV radiation, then lpha is determined by

$$\alpha = \frac{1}{\eta_{\chi}} \ln \frac{g_0}{g}$$
= constant for $\eta < 7 \times 10^{17} \frac{\text{particles}}{\text{cm}^2}$. (6.30)

From the semi-log plot of g vs. η_{χ} , α = 4.4 x 10^{-18} cm² in the linear region. For altitudes greater than 130 km, atomic oxygen is the dominant species so that the depth of penetration of the solar ionizing radiation depends mainly on the absorption coefficient of oxygen and its concentration. In the region 120 to 130 km, conditions in the atmosphere are changing as N_2 and O_2 become more predominant. Approaching 130 km, the production of O_2^+ increases as a fraction of the total production of photoions because the more abundant O and N_2 have absorbed out those wavelengths, causing high production of O^{+} and N_{2}^{+} at higher altitudes. In the range, 120 to 130 km, α depends on z. From the shape of the curve, the effective absorption coefficient has decreased. In the region where α is changing, it may not be possible to read the emission rate factors off Figure 6.2 for other zenith angles and model atmospheres with great accuracy. This is because α is a function of altitude and not just dependent on the slant column density. Thus, the emission rate factors can be determined from this chart for $\eta_{_{\rm Y}} < 7 \times 10^{17} \ {\rm particles/cm}^2$.

In Table 6.1 the values of $\rm g_{_{\rm O}}$ at an altitude of 300 km are given for the transitions, whose emission cross-sections were determined in this experiment.

TABLE 6.1
Emission Rate Factors at 300 km

λ (Å)	Band or Feature	$ \frac{g}{o} $ $ \left(\frac{\text{photons}}{\text{sec molecule}} \right) $
1200	NI	8.19×10^{-10}
1298	(5,0)	1.30×10^{-9}
1325	(4,0)	2.54×10^{-9}
1353	(3,0)	2.62×10^{-9}
1383	(2,0) + (5,2)	2.44×10^{-9}
1464	(1,1) LBH	1.43×10^{-9}
1493	(3,3) LBH + NI	1.32×10^{-9}
LBH TOTAL		4.94×10^{-8}

In Table 6.2 the model atmosphere of Dalgarno, McElroy and Stewart is given, where the column densities for the individual species are the vertical column densities.

6.3 The Aurora.

In a recent paper Rees (1969) has calculated differential electron fluxes for the auroral oval using the data of Hoffman (1969). The principal initial energy loss process of the primary electrons is ionization of the neutral species. Excitation of electronic levels in the un-ionized atmospheric gas are produced principally by secondary electrons. Spectral features such as the 1200 Å, 1493 Å and 1743 Å multiplets of NI, which are partly caused by ionization processes, are probably excited by both the secondary and primary electrons. The production of excited atmospheric species is given by Eqn. 6.10, where Φ now represents the auroral energy flux. The emission rate factor is

$$g_{jk} = \int_{\epsilon_T}^{\infty} \Phi(\epsilon) Q_{jk}(\epsilon) d\epsilon$$
 (6.31)

For illustrative purposes, emission rate factors are calculated for the LBH band system and the nitrogen lines using Eqn. 6.11 and are presented in Table 6.3. The calculation uses the auroral differential energy flux for the auroral oval, as determined by Rees at an altitude of 150 km.

H TOTAL		5.77×10^{-9}

The emission rate factors are true for only this particular auroral oval observation, since the primary auroral flux will, in general, be different for another aurora. The shape of the secondary electron flux spectrum will be approximately the same although its magnitude depends on the intensity of the primary flux.

The computations use only the low energy, or secondary electron flux (less than 100 eV), since the emission cross-sections were measured in the secondary electron region. The calculations are expected to be a good approximation to the LBH production rate and hence, emission rate, since most of the excitation is produced by secondary electrons. However, the emission rate factors for the nitrogen lines probably underestimates the actual emission rate by a factor of 2 or 3, since a substantial part of the emission is caused by dissociative excitation ionization of N_2 by the high energy primary electrons. Cross-sections are not available for this energy region.

CHAPTER VII

SUMMARY

7.1 The Electron Beam Excitation Chamber.

An electron beam excitation chamber has been designed and constructed for measuring emission cross-sections of gases by electron impact for both electric dipole and magnetic dipole transitions. The radiation detection system consisted of a McPherson 218 monochromator and 541 G-08-18 photomultiplier. This system is capable of measuring radiation in the vacuum ultraviolet and other spectral regions with a change of the grating and the photomultiplier. The instrument was calibrated absolutely for radiation in the region, 1200 Å to 2000 Å, by measuring the quantum efficiency times gain of the photomultiplier at 1216 Å with an NO ionization cell, and relative to 1216 Å at other wavelengths by a sodium salicylate comparison. The monochromator was calibrated with a double monochromator arrangement. The steady-state electron beam excitation spectrum of N_{2} in the vacuum ultraviolet has been studied for monoenergetic electrons from 10 eV to 208 eV. The LBH transition of N_2 , and several dissociative transitions, were excited. The geometrical problem of determining the fraction of the LBH spontaneous radiation detected was solved. The problem stems from the forbidden nature of the LBH transition (a magnetic dipole transition). Thus, an $\rm N_2$ molecule, excited to the a $^{\rm l}\,\rm I_{\rm g}$ state by electron impact, can travel several centimeters before radiating. The profile of the LBH radiation as a function of distance from the electron beam in a molecular flow regime is a glow of cylindrical symmetry, most intense at the beam. This phenomenon of molecular flow of an excited LBH molecule dictated that the excitation chamber had to be large so as to preclude wall effects. The dissociatively excited transitions of atomic nitrogen studied were permitted electric dipole transitions and did not have a molecular flow problem, but could be studied with this design.

7.2 The Observations.

The emission cross-section of the a¹ II_g electronic state of molecular nitrogen was determined from 10 eV to 208 eV for monoenergetic electrons. The primary measured data was the emission cross-section of each of the vibrational bands of the LBH band system (approximately 65). The emission cross-section of each vibrational transition was summed to give the emission cross-section for each vibrational level and for the total electronic transition. The maximum cascade contribution to the apparent cross-section is 29%. The actual cascade contribution is probably much less since the measured fraction of the total cross-section contributed by each vibrational level agrees with the fraction calculated by assuming

direct electron excitation of the a $^{1}\Pi_{g}$ state. The peak measured cross-section is at 15.5 eV $_{\pm}$ 1.5 eV and has a value of 3.85 x 10 $^{-17}$ cm 2 for the total electronic transition. Each of the bands has the same relative cross-section shape with energy.

The emission cross-section of the multiplets of atomic nitrogen at 1200 Å, 1493 Å and 1743 Å, by dissociative excitation of N_2 , was measured. These cross-sections typically had two thresholds, one at about 20 eV due to dissociative excitation of N_2 , and the other at about 35 eV due to dissociative ionization excitation of $\rm N_2$. The 1493 Å multiplet and the 1743 Å multiplet originated from the same electronic level. Their measured cross-sections were in the ratio as predicted by a branching ratio calculation. The peak cross-section for the dissociative excitation transitions is at about 110 eV, with dissociative ionization excitation being the more important process for electron energies greater than 50 eV. The emission cross-section of the λ = 1200 Å multiplet was the emission cross-section for the ⁴P state of atomic nitrogen due to dissociative excitation of molecular nitrogen. The emission crosssection of the λ = 1743 Å multiplet and the 1493 Å multiplet were summed to give the emission cross-section of the ²P state of atomic nitrogen due to dissociative excitation of molecular nitrogen.

7.3 <u>Atmospheric Calculations</u>.

The measured emission cross-sections of $\rm N_2$ were applied to the photoelectron excited dayglow and the auroral oval. The emission rate factor was calculated for the LBH band system and the nitrogen lines in the dayglow as a function of slant abundance. The emission rate factor was calculated for the auroral oval at 150 km altitude.

APPENDIX A

A Description of the Electron Beam Excitation Chamber.

The excitation chamber is 10 3/8 inches long and 8 inches in outside diameter. The walls were 1/4 inch thick. The end flanges for the chamber were Varian 954-5064 stainless steel blank conflat flanges, 10 inches in diameter and 0.96 inches thick. The flanges were drilled on center for a 1 1/4 inch hole. A specially designed electrical feed-through was welded to the flange in the hole. On the feed-through were eight nickel pins to provide electrical continuity between the electron gun and collector and the appropriate outside electronics. The feed-through was ceramic (aluminum oxide) to which kovar expansion sleeves were inserted around the nickel pins and around the outside diammeter of the feed-through. All seals for the feed-through were made by a copper braze.

The chamber and vacuum system was specially constructed by Granville Phillips Company of Boulder, Colorado, for this experiment. The various ports on the chamber were as follows.

(1) Gas Inlet: The gas inlet port was connected to the chamber by a 1/4 inch outside diameter and 1/8 inch inside diameter stainless steel tubing, which was

welded to the chamber. A 2 inch baffle was placed at the inlet port to provide a well diffused flow of nitrogen into the chamber. Matheson prepurified nitrogen was used as the gas source. Between the gas and the chamber was a Granville Phillips automatic pressure controlling leak valve, used to control the pressure in the chamber.

- on the chamber so as to view the center of the interaction region of the chamber. The port was a 2 inch outside diameter pipe of 0.65 inches wall thickness welded to the chamber. It was 2 1/2 inches long and had a 4 1/2 inch conflat rotatable flang set in it. Various size nipples were made to bolt onto this flange to control the distance from the spectrometer entrance slit to the chamber. A special two-faced flange provided adaptation between the Granville Phillips flange and the McPherson flange. The distance between the center of the excitation chamber and the entrance slit on the spectrometer, decided upon for this experiment, was 9 13/16 inches.
- (3) Gas outlet port: The gas outlet port was 2 inches in outside diameter. It let to the pumps, gate valve and pressure measuring gauges.

- (4) High pressure measuring port: This port was open only during initial pump-down and led to a Wallace-Tiernan gauge, capable of measuring pressure from 1 to 20 torr. A C-valve (Granville Phillips trademark) was used to seal the gauge from the chamber when low pressure (less than 1 torr) was reached.
- (5) Viewing port: A 2 1/2 inch wide angle quartz
 window was placed on top of the chamber in the
 center of the interaction region so as to "view" the
 beam. This port could be used for photographic purposes in the visible and infrared. It also provided
 information about the collimation of the beam.
- (6) Auxiliary port: An auxiliary port, sealed by a 2 1/2 inch conflat flange, was provided as an accessory. It could be used for pressure calibration or to admit a buffer gas.

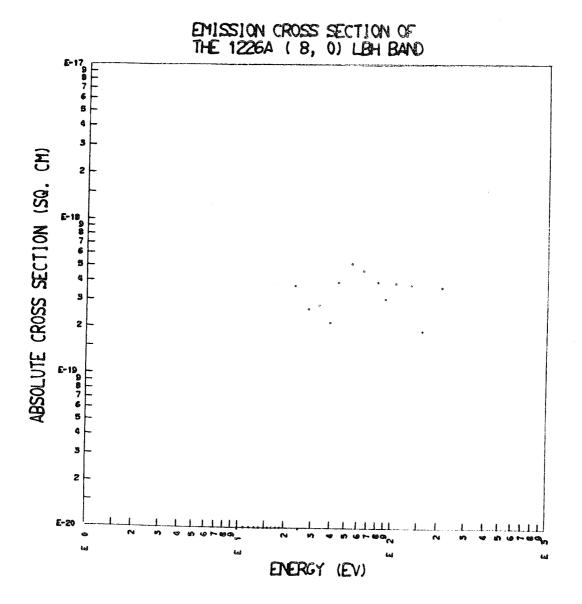

On the side of the chamber directly opposite the spectrometer port, an aluminum sheet, .020 inch and 5 inches square, was placed and shaped to the wall. It had a gold black deposit of about $50 \times 10^{-6} \, \mathrm{gm/cm^2}$. It was prepared by evaporating gold into the aluminum plate in a nitrogen atmosphere. It is a very porous structure of colloidal gold particles about 100 Å in diameter

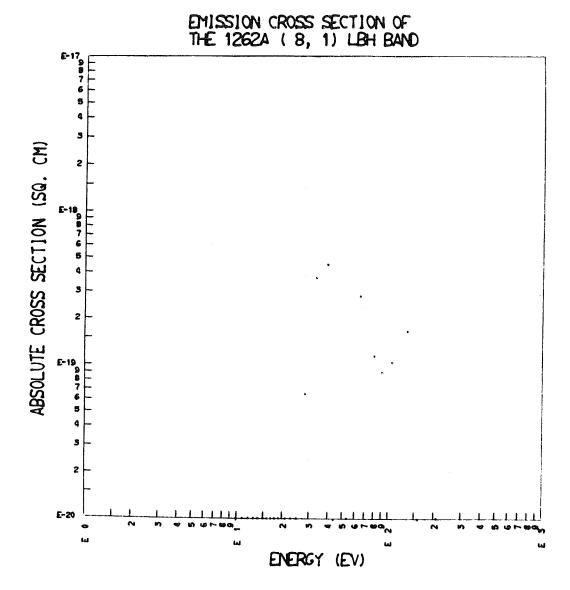

(Harris and Beasley, 1952). These particles adhere together to form chains and aggregates. This structure was used to absorb the ultraviolet radiation, preventing detection of reflected ultraviolet radiation.

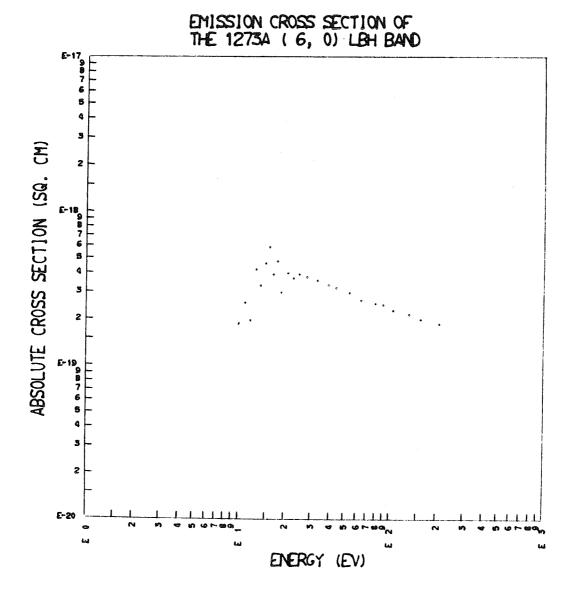

The entire chamber was submitted to a 24-hour, 500 °C bakeout before operation. Four mounting tapped holes were placed on each 10-inch flange to facilitate mounting of the electron gun and collector.
